Laboratory investigation showed dissociation of serum transaminase activities (increased glutamic oxaloacetic transaminase and normal glutamic pyruvic transaminase), a feature which is also seen in other CDG-II group patients. IEF of serum transferrin showed a type 2 pattern (with nearly absent tetrasialo-transferrin) and structural analysis of the transferrin oligosaccharides, a monoantennary N-acetyllactosamine-type glycan. Thus, contrary to the structurally normal sialotransferrins in the CDG-I group or assembly disorders, the sialotransferrins of this and some other CDG-II diseases have abnormal glycan structures.

No efficient treatment is available.

Inheritance is autosomal recessive.

## 94.3 CONGENITAL DISORDERS OF PROTEIN O-GLYCOSYLATION

Eleven defects have been identified: one in O-N-acetylglactosaminylglycan synthesis (GALNT3-CDG or familial hyperphosphatemic tumoral calcinosis), four in O-xylosylglycan synthesis (B4GALT7-CDG or progeroid variant of Ehlers–Danlos syndrome, EXT1-CDG and EXT2-CDG (hereditary multiple exostoses) and CHSY1-CDG

or Tentamy preaxial brachydactyly syndrome), one in O-xylosyl/O-N-acetylglactosaminylglycan synthesis (SLC35D1-CDG or Schneckenbecken dysplasia), three in O-mannosylglycan synthesis (POMT1-CDG or muscular dystrophy-dystroglycanopathy types A1, B1 and C1, POMT2-CDG or muscular dystrophy-dystroglycanopathy types A2, B2 and C2, and POMGNT1-CDG or muscular dystrophy-dystroglycanopathy types A3, B3 and C3), and two in O-fucosylglycan synthesis (LFNG-CDG or spondylocostal dysostosis type 3, and B3GALTL-CDG or Peters plus syndrome) (Table 94-2). Except for the progeroid variant of Ehlers–Danlos syndrome, these are well-known diseases that very recently have been recognized as glycosylation disorders. They are hereby shortly summarized.

### 94.3.1 GALNT3-CDG (Familial Hyperphosphatemic Tumoral Calcinosis)

Patients suffer from recurrent, painful calcified subcutaneous masses that can attain up to 1 kg in weight (12). This can be complicated by secondary infections and incapacitating mutilations.

The basic defect is in isoform 3 of the N-acetylglactosaminyltransferase (GalNAcT3) family, which comprises more than 20 members. This enzyme mediates O-glycosylation of fibroblast growth factor 23 (FGF23), thereby protecting it from degradation through proteolysis. FGF23 is a phosphatonin that functions by decreasing the expression of the renal phosphate transporter. Mutations of GalNAcT3 result in decreased FGF23 activity and thus in increased phosphate reabsorption and hyperphosphatemia.

No efficient treatment is available.

Inheritance is autosomal recessive.

**TABLE 94-2 Genetic Protein O-Glycosylation Disorders**

Disease	Affected Protein	Defective Gene	OMIM Number
<i>Defect in O-N-Acetylglactosaminylglycan Synthesis</i>			
GALNT3-CDG	N-acetylglactosaminyltransferase 3	<i>GALNT3</i>	211900
<i>Defects in O-Xylosylglycan Synthesis</i>			
B4GALT7-CDG	Beta-1,4-galactosyltransferase 7	<i>B4GALT7</i>	130070
EXT1-CDG	Exostosin 1	<i>EXT1</i>	130700
EXT2-CDG	Exostosin 2	<i>EXT2</i>	130701
CHSY1-CDG	Chondroitin sulfate synthase	<i>CHSY1</i>	605282
<i>Defect in O-N-Acetylglactosaminylglycan and O-Xylosylglycan Synthesis</i>			
SLC35D1-CDG	UDP-glucuronic acid/UDP-N-acetylglactosamine dual transporter	<i>SLC35D1</i>	269250
<i>Defects in O-Mannosylglycan Synthesis</i>			
POMT1-CDG	O-mannosyltransferase 1	<i>POMT1</i>	236670, 613155, 609308
POMT2-CDG	O-mannosyltransferase 2	<i>POMT2</i>	613150, 613156, 613158
POMGNT1-CDG	O-mannose beta-1,2-N-acetyl-glucosaminyltransferase	<i>POMGNT1</i>	253280, 613151, 613157
<i>Defects in O-Fucosylglycan Synthesis</i>			
LFNG-CDG	O-fucose-specific beta-1,3-N-acetylglucosaminyltransferase	<i>LFNG</i>	609813
B3GALTL-CDG	O-fucose-specific beta-1,3-N-glucosyltransferase	<i>B3GALTL</i>	261540

### 94.3.2 EXT1/EXT2-CDG (Hereditary Multiple Exostoses)

These are characterized by osteochondromas of the ends of long bones. The tumors are often present at birth, their growth slows during adolescence and stops in adulthood. Only a small percentage of these lesions show malignant degeneration. Compression of peripheral nerves and blood vessels may cause complications (13).

The basic defect is in the Golgi-localized EXT1/EXT2 complex, which has both glucuronyltransferase and N-acetyl-D-hexosaminyltransferase activities involved in the polymerization of heparan sulfate. Evidence has been presented linking the development of the exostoses to activation of Indian hedgehog signaling during embryonic chondrocyte differentiation.

This is the only known CDG with autosomal-dominant inheritance.

No basic treatment is available.

### 94.3.3 SLC35D1-CDG (Schneckenbecken Dysplasia)

This is a severe skeletal dysplasia comprising mainly platyspondyly, extremely short long bones, and small ilia with snail-like appearance (14).

The solute carrier encodes an ER UDP-glucuronic acid/UDP-N-acetylgalactosamine dual transporter needed for chondroitin sulfate biosynthesis.

Inheritance is autosomal recessive.

No efficient treatment is available.

### 94.3.4 POMT1/POMT2-CDG (O-Mannosyltransferase 1 Deficiency, O-Mannosyltransferase 2 Deficiency)

These are rare neuronal migration disorders characterized by brain and eye dysgenesis associated with congenital muscular dystrophy. Male patients often have testicular defects. They are very severe diseases that usually run a fatal course before the age of 1 year. Psychomotor development is absent. The brain lesions consist of cobblestone lissencephaly, agenesis of the corpus callosum, cerebellar hypoplasia, hydrocephaly, and sometimes, encephalocoele (15).

In this disorder, there is an aberrant glycosylation of  $\alpha$ -dystroglycan, an external membrane protein expressed in muscle, brain and other tissues. Most glycans of this heavily glycosylated protein seem to be O-linked through mannose, and they control the interaction with extracellular matrix proteins. Disrupted glycosylation of  $\alpha$ -dystroglycan (and probably other glycoproteins) results in loss of this interaction, and hence, in progressive muscle degeneration and abnormal neuronal migration (overmigration) in the brain. A minority of patients with this syndrome show mutations in the *POMT1* gene coding for protein

O-mannosyltransferase-1. This enzyme catalyzes the first step in the synthesis of the O-mannose-linked core Gal $\beta$ 1-4GlcNAc $\beta$ 1-2Man-O-Ser/Thr.

No efficient treatment is available.

Inheritance is autosomal recessive.

### 94.3.5 POMGNT1-CDG (O-Mannose Beta-1,2-N-Acetylglucosaminyltransferase Deficiency)

This is a neuronal migration or congenital muscular dystrophy syndrome similar to POMT1/POMT2-CDG but less severe. As in the latter syndromes, skeletal muscle shows almost no  $\alpha$ -dystroglycan by Western blotting and immunohistochemical analysis with an antibody that recognizes a glycosylated epitope (15).

These patients show mutations in the gene encoding protein O-mannosyl- $\beta$ 1,2-N-acetylglucosaminyltransferase 1, catalyzing the second step in the synthesis of the O-mannosylglycan core.

No efficient treatment is available.

Inheritance is autosomal recessive.

### 94.3.6 LFNG-CDG (Spondylocostal Dysostosis Type 3)

Patients show a severe vertebral phenotype with malsegmentation due to disruption of somitogenesis. Somites are precursors of the axial skeleton and of the associated musculature (16).

This is a notch pathway defect in Lunatic Fringe, an O-fucose-specific  $\beta$ 1,3-N-acetylglucosaminyltransferase. Of note is that spondylocostal dysostosis type 1 and type 2 are also due to defects in the notch pathway.

No efficient treatment is available.

Inheritance is autosomal recessive.

### 94.3.7 B3GALT1-CDG (Peters Plus Syndrome)

Patients show peculiar eye malformations including corneal opacities and iridocorneal adhesions besides growth retardation and variable abnormalities in other organs (17).

Mutations are in a  $\beta$ 1,3-glucosyltransferase that adds glucose to O-linked fucose. This disaccharide modification is specific to thrombospondin type 1 repeats, found in extracellular proteins that function in cell-cell and cell-matrix interactions.

No specific treatment is available.

Inheritance is autosomal recessive.

## 94.4 CONGENITAL DISORDERS OF PROTEIN N- AND O-GLYCOSYLATION

Eighteen disorders have been reported (Table 94-3). The five most frequent are described here.

**TABLE 94-3 TA Genetic Protein Combined N- and O-Glycosylation Disorders**

Disease	Affected Protein	Defective Gene	OMIM Number
DPM1-CDG	GDP-Man:Dol-P-mannosyltransferase 1	<i>DPM1</i>	608799
DPM3-CDG	GDP-Man:Dol-P-mannosyltransferase 3	<i>DPM3</i>	612937
MPDU1-CDG	Dol-P-Man utilization 1	<i>MPDU1</i>	609180
B4GALT1-CDG	Beta-1,4-galactosyltransferase 1	<i>B4GALT1</i>	607091
GNE-CDG	UDP-GlcNAc epimerase/kinase	<i>GNE</i>	600737, 605820
SLC35A1-CDG	CMP-sialic acid transporter	<i>SLC35A1</i>	603585
SLC35C1-CDG	GDP-fucose transporter	<i>SLC35C1</i>	266265
DK1-CDG	Dolichol kinase	<i>DK1</i>	610768
SRD5A3-CDG	Steroid 5-alpha-reductase	<i>SRD5A3</i>	612379
DHDDS-CDG	Dehydrodolichyl-PP synthase	<i>DHDDS</i>	613861
COG7-CDG	COG complex 7	<i>COG7</i>	608779
COG1-CDG	COG complex 1	<i>COG1</i>	611209
COG8-CDG	COG complex 8	<i>COG8</i>	611182
COG4-CDG	COG complex 4	<i>COG4</i>	613489
COG5-CDG	COG complex 5	<i>COG5</i>	613612
COG6-CDG	COG complex 6	<i>COG6</i>	606977
ATP6V0A2-CDG	Vesicular H <sup>+</sup> -ATPase $\alpha$ 2	<i>ATP6V0A2</i>	219200, 278250
SEC23B-CDG	COPII component SEC23B	<i>SEC23B</i>	224100

#### 94.4.1 GNE-CDG (Hereditary Inclusion Myopathy, Nonaka Myopathy)

This myopathy has an adult onset with progressive distal and proximal muscle weakness. A peculiar feature is that it spares the quadriceps muscles. Muscle histology shows rimmed vacuoles on Gomori's trichrome stain, small fibers in groups and tubulofilaments without evidence of inflammation (18). The gene encodes a bifunctional enzyme that catalyzes the first two (and rate-limiting) steps in sialic acid biosynthesis.

Trials with oral sialic acid precursors are underway in a mouse model.

Inheritance is autosomal recessive.

#### 94.4.2 SRD5A3-CDG (Steroid 5-Alpha-Reductase Deficiency)

Fifteen patients belonging to seven families have been reported. Besides psychomotor retardation, the most prominent symptoms are cerebellar (atrophy, vermis malformations), ophthalmological (hypoplasia or coloboma of the iris, retina, choroid, optic disc; nystagmus, optic atrophy, microphthalmia, glaucoma, cataract) and cutaneous (ichthyosis, erythroderma, dry skin, atopic dermatitis) (19). This is the second reported defect in the synthesis of dolichol phosphate, more specifically in the conversion of pre-dolichol to dolichol.

No therapy is currently available.

Inheritance is autosomal recessive.

#### 94.4.3 COG7-CDG (COG Complex 7 Deficiency)

The conserved oligomeric Golgi (COG) complex is an eight-subunit (COG1-8) peripheral Golgi membrane hetero-oligomeric protein complex. It is organized into

lobes A (COG2-4) and B (COG5-7) with COG1 and COG8 bridging these lobes. This complex is thought to play a critical role in vesicle tethering processes involving retrograde Golgi transport of resident proteins responsible for glycan biosynthesis. Defects have been reported in COG1 (COG1-CDG), COG7 (COG7-CDG), COG8 (COG8-CDG), COG4 (COG4-CDG), COG5 (COG5-CDG) and COG6 (COG6-CDG). The seven reported COG7-deficient patients were all of North African origin. They had a lethal disorder (six of them died in their first year of life) and showed in addition hyperthermia, ventricular/atrial septum defect, and cholestatic liver disease (20). Studies of fibroblast glycoproteins showed a partial N- and O-glycosylation defect caused by a decreased transport of CMP-sialic acid and UDP-galactose into the Golgi, and a reduced activity of two glycosyltransferases involved in the galactosylation and sialylation of O-glycans. The six patients with early lethality were homozygous for the same intronic mutation in *COG7*.

No therapy is currently available.

Inheritance is autosomal recessive.

#### 94.4.4 ATP6V0A2-CDG (Autosomal Recessive Cutis Laxa Type IIA, Wrinkly Skin Syndrome)

These patients have generalized cutis laxa at birth that becomes less obvious with age.

They also present with increased joint laxity, ophthalmological abnormalities (mainly strabismus, myopia or amblyopia, and sometimes corneal dystrophy), microcephaly, and delayed motor development that improves with age (21).

The defect is in the  $\alpha$ 2 subunit of the vesicular H<sup>+</sup>-ATPase pump. Tropoelastin aggregates are found in their Golgi apparatus.

No therapy is currently available.

### 94.4.5 SEC23B-CDG (Congenital Dyserythropoietic Anemia Type II)

Congenital dyserythropoietic anemia type II (CDAIL) has recently been shown to be due to mutations in the gene coding for SEC23B, a COPII component (22).

The disorder is limited to the erythroblastic lineage most probably because in the other tissues, a SEC23A isoform compensates for the SEC23B deficiency.

No efficient treatment is available.

Inheritance is autosomal recessive.

## 94.5 PERSPECTIVES

The field of CDG continues to grow at a rapid rate. Some 50 CDG have been unraveled in the course of 30 years. Major developments are to be expected in the following areas: defects in dolichol metabolism, defects in lipid glycosylation, defects in organ-specific glycosylation, and defects in other multifunctional proteins, i.e. proteins that are involved not only in glycosylation but also in other functions. Advances in treatment are eagerly awaited since an efficient treatment is available for only one CDG (MPI-CDG). Efforts should be directed, in particular, toward a therapy for the important and often devastating disorder, PMM2-CDG. Since about 1% of the human genome is devoted to glycosylation, it is evident that we know only a small minority of existing CDG. The search for novel CDG will, at the same time, greatly booster our knowledge of the many unknown aspects of this most important protein (and lipid) modification.

### Biography

Jaak Jaeken, MD, PhD, is an Emeritus Professor of Pediatrics at the University of Leuven, Belgium. He is a specialist in metabolic diseases and his main interest is in congenital disorders of glycosylation (CDG) which he first described in 1980. He is actively involved in the study of all aspects of this rapidly growing family of metabolic diseases with some 55 diseases actually known. Since about 1% of the human genome is devoted to glycosylation, it is to be expected that the majority of CDG has still to be discovered. Jaak Jaeken received in 1999 the degree of Doctor Honoris Causa from the University of Zurich, and in 2000 from the University of Havana.

### GLOSSARY

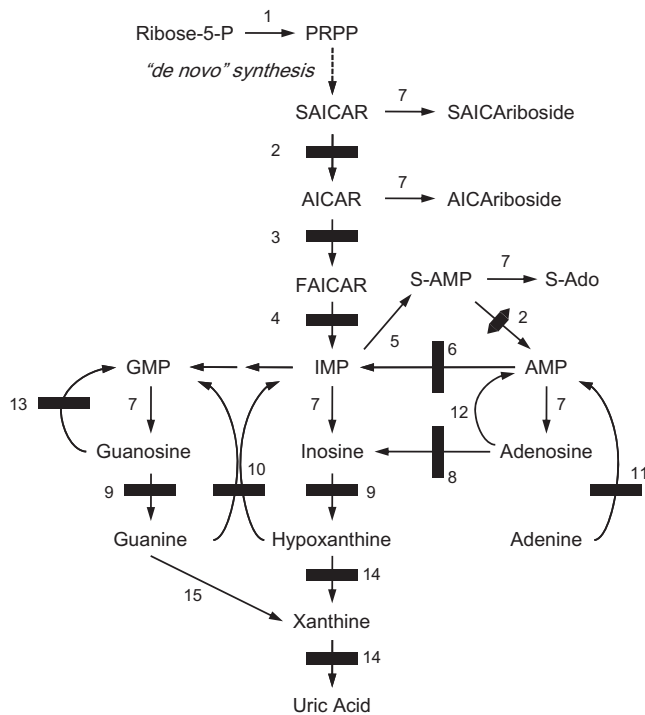

**GWAS** – Genome-wide association study is a method to identify genes or genomic variations associated with traits such as diseases, drug reactions, physical measures, and laboratory test values. In GWAS (sometimes called whole-genome association study or WGA), the associations between a trait and more than 100,000 single-nucleotide polymorphisms (SNPs) spanning the whole genome are statistically analyzed. Careful collection of samples and data from many individuals, powerful and high-speed genotyping machines, and computer programs are the keys of the study.

### 95.1 INTRODUCTION

The study of disorders of purine and pyrimidine metabolism began in the nineteenth century. In 1848, A.B. Garrod (1) found that gouty arthritis is associated with uric acid. In the following century, his son, A.E. Garrod (2), who first introduced the concept of an “inborn error of metabolism,” listed gout among the first diseases that implicated inborn factors. In 1964, Lesch-Nyhan syndrome was reported as an inherited disease and a deficiency of hypoxanthine–guanine phosphoribosyltransferase (HGPRT or HPRT) was discovered a few years later (3). Subsequently, the following purine enzyme

abnormalities were found: adenine phosphoribosyltransferase deficiency (4,5), phosphoribosyl pyrophosphate (PRPP) synthetase superactivity (6), adenosine deaminase (ADA) deficiency (7), purine nucleoside phosphorylase deficiency (8), enzyme deficiencies associated with xanthinuria (9,10), adenylosuccinate lyase deficiency (11), myoadenylate deaminase deficiency (12), ATIC deficiency (13), thiopurine methyltransferase deficiency (14), and deoxyguanosine kinase deficiency (15). The following pyrimidine enzyme abnormalities were found: UMP synthase deficiency (16), dihydropyrimidine dehydrogenase deficiency (17), dihydropyrimidinase deficiency (18),  $\beta$ -ureidopropionase deficiency (19), pyrimidine 5'-nucleotidase deficiency (20), cytosolic 5'-nucleotidase superactivity (21), thymidine phosphorylase deficiency (22), dihydroorotate dehydrogenase deficiency (23), cytidine deaminase deficiency (24), and thymidine kinase 2 deficiency (25).

In the 1980s and 1990s, molecular biology techniques were used to identify the mechanisms for the reported enzyme deficiencies at the DNA and RNA levels, and the precise changes in the genes were identified. In the 2000s, in addition to the previous candidate gene approach, genome-wide approaches were used to discover the genetic causes of gout and hyperuricemia. Thus, the uromodulin (*UMOD*) gene abnormality was discovered

**FIGURE 95-1** Pathways of purine metabolism. AICAR, aminoimidazole carboxamide ribotide; AMP, adenosine monophosphate; FAICAR, formylaminoimidazolecarboxamide ribotide; GMP, guanosine monophosphate; IMP, inosine monophosphate; P, phosphate; PRPP, phosphoribosyl pyrophosphate; S-Ado, succinyladenosine; SAICAR, succinylaminoimidazolecarboxamide ribotide; S-AMP, adenylosuccinate; XMP, xanthosine monophosphate. 1, PRPP synthetase; 2, adenylosuccinate lyase (adenylosuccinase); 3, AICAR transformylase; 4, IMP cyclohydrolase (3 and 4 form ATIC); 5, adenylosuccinate synthetase; 6, AMP deaminase; 7, 5'-nucleotidase(s); 8, adenosine deaminase; 9, purine nucleoside phosphorylase; 10, hypoxanthine-guanine phosphoribosyltransferase; 11, adenine phosphoribosyltransferase; 12, adenosine kinase; 13, guanosine kinase; 14, xanthine oxidase (dehydrogenase); 15, guanine deaminase. Enzyme defects are indicated by solid bars.

by linkage analysis (26,27) and many genes including *SLC22A12*, *SLC22A11*, *SLC2A9*, *ABCG2*, *SLC17A1*, *WDR1*, *GCKR*, *PDZK1*, *R3HDM2-INHBC* region, *RREB1*, and *LRP2* were found to be associated with serum urate concentrations by genome-wide association studies (GWASs) (see Section 95.2.2.4). The latter genes, many of which code for either the transporters in renal tubules or related proteins, are considered to constitute polygenic factors for hyperuricemia.

Monogenic disorders of purine metabolism (Figure 95-1) are known to be responsible for a wide variety of clinical conditions, including kidney stones of various compositions (5,9,28), immunodeficiency diseases (7,8), exercise intolerance (12), and a number of devastating neurologic syndromes (3,10,11,13,29). Inborn errors of pyrimidine metabolism have been found to be responsible for megaloblastic anemia (16), hemolytic anemia (20), and various mental and neurologic disorders (18,19,21,30,31,32).

Thiopurine methyltransferase (33) and dihydropyrimidine dehydrogenase (34) deficiencies have provided

major contributions to the emerging field of pharmacogenomics. In recent years, deficiencies of enzymes for purine and pyrimidine metabolism have been identified in mitochondrial disorders (15,25,35).

For ADA deficiency, enzyme replacement therapy and somatic gene therapy are very effective at improving the severe immunodeficiency symptoms of patients (see Section 95.2.7.5).

In this chapter, a survey of the partly genetically determined disorder, gout, is followed by overviews of the inborn errors of metabolism that have been discovered in the purine and pyrimidine metabolic pathways.

## 95.2 PURINE METABOLISM

### 95.2.1 Metabolic Pathways

Purine nucleotides are essential cellular constituents that are involved in energy transfer, metabolic regulation, and the synthesis of DNA and RNA. Purine metabolism can be divided into three pathways (see Figure 95-1):

The biosynthetic pathway, often termed the *de novo* pathway, starts after the formation of the high-energy compound PRPP, and leads to the synthesis of inosine monophosphate (IMP) in 10 steps (not shown in detail in Figure 95-1). From IMP, two reactions lead to the formation of adenosine monophosphate (AMP). Subsequently, adenosine diphosphate (ADP) and adenosine triphosphate (ATP), and their deoxy counterparts (not shown in Figure 95-1) are formed. Two other reactions convert IMP into guanosine monophosphate (GMP), from which guanosine diphosphate (GDP), guanosine triphosphate (GTP), and their deoxy counterparts (not shown in Figure 95-1) are formed.

The purine catabolic pathway starts from GMP, IMP, and AMP, and produces uric acid, a poorly soluble compound that tends to crystallize once its plasma concentration surpasses 6.5–7.0 mg/dL (0.38–0.47 mmol/L).

The purine salvage pathway uses the purine bases guanine, hypoxanthine, and adenine, which are provided by food intake or the catabolic pathway, and reconverts them into GMP, IMP, and AMP, respectively. Salvage can also occur by the phosphorylation of nucleosides such as adenosine.

### 95.2.2 Gout

Gout is a common disorder caused by the formation of urate crystals in the body. These may result in crystal-induced arthritis, tophi formation, urolithiasis, and kidney disease. Urate crystals may form in the body when the concentration of urate exceeds the limit of solubility (~7.0 mg/dL in plasma at 37°C). Most mammalian species possess the urate-degrading enzyme urate oxidase and, hence, have rather low plasma concentrations of urate. The human genome contains the sequence for urate oxidase, but the gene has stopped functioning

owing to at least three deleterious mutations (36). Due to this deficiency in urate oxidase, humans tend to display plasma urate levels above the limit of solubility, and some individuals with serum urate concentrations  $>7.0$  mg/dL develop gout.

**95.2.2.1 Epidemiology.** Hyperuricemia (usually defined as a urate serum concentration  $>7.0$  mg/dL in men and  $>6.0$  mg/dL in women or  $>7.0$  mg/dL in both genders) does not necessarily indicate the presence of gout; however, the higher the serum urate concentration, the higher the incidence of gout (37). Serum urate concentrations are affected by various factors such as ethnicity, sex, age, social status, habits, and body weight. The prevalence of gout or hyperuricemia was reported to have recently increased in the United States (38,39), Europe (40,41), Saharan Africa (42), and Asian countries (43,44). The average serum urate concentration in men is  $\sim 1.0$ – $1.5$  mg/dL higher than in women. In men, the serum urate concentration increases during puberty and stays at the same level thereafter, whereas it increases after the menopause in women. Therefore, gout is primarily a disease affecting adult males and postmenopausal adult females. The proportion of women among patients with gout is  $\sim 5\%$ , although this statistic varies between reports.

Genetic and environmental factors are associated with hyperuricemia and gout. There is ample evidence indicating that various environmental factors, such as alcohol ingestion and the consumption of meat and seafood, are associated with gout (45,46). The heritability of serum urate levels has been estimated to be 0.7–0.8, and a recent GWAS has successfully identified some of these genetic factors (see Section 95.2.2.4).

**95.2.2.2 Clinical Features.** *Presentation.* Patients with gout usually experience three stages: asymptomatic hyperuricemia, followed by intermittent episodes of gout, and, finally, chronic tophaceous gout. After several years of asymptomatic hyperuricemia, the first episode of gouty arthritis often occurs suddenly, usually in healthy men.

Acute gouty arthritis, often called a gouty attack, is the most prominent clinical feature of the second stage. It is characterized by (a) sudden onset; (b) the presence of aura (abnormal sense around the affected joint) before the initiation of inflammation; (c) monoarthritis; (d) marked inflammation accompanied by redness, warmth, swelling, and severe pain; (e) peak inflammation within 24 h after onset; and (f) almost complete relief of inflammation within 7 days. In  $\sim 50$ – $70\%$  of cases, the first gouty attack occurs in the first metatarsophalangeal joint (podagra), but other common sites include the insteps, ankles, heels, knees, wrists, finger joints, and elbows. Later, the arthritis may become polyarticular, last for more than a week, not subside completely, and be accompanied by fever. Laboratory findings include elevated C-reactive protein, sedimentation rate, and white blood cell count.

In the intermittent stage of gout, that is during the intercritical periods between attacks, an almost complete

remission of symptoms is observed. The second attack usually occurs within 6 months to 2 years of the first. If the hyperuricemic state is not corrected, the frequency of attacks increases.

If gout remains untreated for several years, chronic tophaceous gout may develop. In untreated patients, visible tophi appear at an average of 11.6 years (range 3–42 years) after the initial attack. The interval between gouty attacks becomes unclear and patients suffer almost continuous pain although the pain is less pronounced than that from acute gouty arthritis. Tophi result from the deposition of monosodium urate monohydrate crystals. In the chronic stage of gout, tophi are increasingly detected in various parts of the body, except the brain. Tophi are most often detected in the helix of the ear, toes, knees, hands and fingers, the ulnar surface of the forearm, and the olecranon bursa. In rare cases, tophi that have formed in the spinal canal, bone marrow, and vocal cords have caused neurologic symptoms, bone fractures, and hoarseness, respectively. Tophi can cause changes that are visible on radiographs; bony erosions due to tophi typically show a punched-out appearance. An overhanging edge of bone is also typical of the changes caused by tophi that can be seen on a radiograph. In severe cases, evidence of massive bone destruction can be seen. If left untreated, tophi may destroy joints, and patients may eventually become crippled although such a progression of the disease is very rare in developed countries where patients can receive proper treatment for hyperuricemia.

Renal disease in patients with gout can be caused by several different mechanisms. Urate nephropathy is a disorder caused by the deposition of urate crystals in the interstitial tissue of the kidneys, whereas uric acid nephropathy is caused by the deposition of uric acid crystals, from urine, in the collecting tubules, renal pelvis, and ureter. Due to the difference in pH (the pH of urine is lower), different types of crystals form in tissue fluid and urine. In addition, other factors such as hypertension and the use of anti-inflammatory drugs can cause renal insufficiency in patients with gout. Clinically, gouty nephropathy is characterized by mild proteinuria and a reduced ability to concentrate urine. If patients receive proper treatment, severe renal insufficiency does not occur in most cases. Patients with familial juvenile hyperuricemic nephropathy (FJHN) are an exception because terminal renal insufficiency may occur even when patients receive proper treatment (Section 95.2.2.4).

*Diagnosis.* Diagnosis of acute gouty arthritis is not difficult when the patient has experienced more than one episode of arthritis. The characteristics of this condition, listed as (a)–(f) in the previous section, enable clinicians to make a correct diagnosis. The most confirmatory test for the diagnosis of acute gouty arthritis is the detection of urate crystals in neutrophils in fluid aspirated from the inflamed joints. Crystals can be detected with a standard microscope; however, the detection of needle-shaped,

negatively birefringent crystals by a polarizing microscope confirms that the component of the crystals is monosodium urate. Although the detection of urate crystals in neutrophils can confirm a diagnosis of gouty arthritis, the finding of urate crystals outside the cells in aspirated synovial fluid and the finding of tophi are also useful in the diagnosis of gout because they show that urate crystals have formed in the body.

Differential diagnoses of acute gouty arthritis include septic arthritis, bacterial cellulitis, and palindromic rheumatism. Inflammation of the first metatarsophalangeal joint, due to hallux valgus, sometimes resembles an acute gouty attack.

**95.2.2.3 Classification.** The plasma urate concentration is determined by its production in the liver and its excretion by the kidneys; hence, hyperuricemia can be caused by two different mechanisms: namely, the overproduction of urate by the liver and the underexcretion of urate by the kidneys. According to these mechanisms, hyperuricemia and gout are classified into three types: an overproduction type, an underexcretion type, and a mixed type.

The overproduction type composes ~10% of all cases. The overproduction and underexcretion types of hyperuricemia may be secondary to another disorder or the administration of drugs. In myeloproliferative disorders and lymphomas, hyperuricemia occurs as a result of urate overproduction. Renal insufficiency and the administration of drugs such as thiazides, loop diuretics, pyrazinamide, cyclosporine A, and low-dose aspirin cause hyperuricemia by provoking the underexcretion of urate. Gout caused by another disorder or by the administration of drugs is called secondary gout, as opposed to primary gout, in which no such conditions are identified.

It is of note that hyperuricosuria can also be associated with hypouricemia, which can be caused by genetic factors.

**95.2.2.4 Molecular Genetics.** *Genetic Basis of Hyperuricemia and Gout.* Although genetic factors play a role in the development of hyperuricemia and gout in many patients, the degree of involvement varies from patient to patient. Mendelian inheritance can be suspected in only a very small proportion of patients with a family history of gout.

A number of inherited enzyme abnormalities result in the early development of the overproduction type of hyperuricemia and gout. Most notably, HGPRT deficiency (3,28) and PPRP synthetase superactivity (6,47), both caused by mutations in two different X-linked genes, lead to marked hyperuricemia and gout (see the corresponding sections in this chapter). In addition, hereditary fructose intolerance and some glycogen-storage diseases, including glucose-6-phosphatase deficiency (glycogen-storage disease type I), debranching enzyme deficiency (type III), muscle phosphorylase deficiency (type V), and muscle phosphofructokinase deficiency (type VII), may also cause episodic or continuous hyperuricemia and, potentially, gout (see Chapter 93) (48).

Recently, genome-wide approaches have been used to identify genes associated with gout and serum urate concentrations; thus, uromodulin gene (*UMOD*)

abnormalities were shown to cause FJHN by linkage analysis (26), followed by a search in the 16p12 chromosomal region for the gene responsible for the disease (27). So far, 64 different mutations have been reported in *UMOD*, most of which cause amino acid substitutions. More than half of these substitutions involve cysteine residues. FJHN is characterized by the gradual deterioration of renal function after adolescence and is accompanied by hyperuricemia and gout (49,50). The disease is inherited as an autosomal dominant trait. In the renal tubules of patients, mutant uromodulin protein accumulates within the endoplasmic reticulum, probably because of a failure to excrete the protein into urine (51,52). The accumulation of uromodulin protein within the tubular epithelia of the thick ascending limb of the loop of Henle, owing to mutations that change the amino acids, is likely to be responsible for the decrease in the excretion of urate in the tubules and for hyperuricemia and renal insufficiency (52). Two additional genes, *REN* (53) and *HNF-1 $\beta$*  (54), have been identified as disease loci for FJHN.

*Genetic Basis of Hypouricemia.* Inherited renal hypouricemia has long been reported (55,56). Serum urate concentrations in typical cases are <2.0 mg/dL. This genetic defect can lead to urolithiasis (57) and acute renal failure after exercise (58). Homozygous mutations in *SLC22A12* (59–61) and homozygous and heterozygous mutations in *SLC2A9* (62), which code for renal transporters, were discovered in subjects with hypouricemia.

Although most cases of gout or hyperuricemia are thought to be multifactorial, the search for the genes associated with such conditions had been unsuccessful because of the lack of power of linkage analysis for multifactorial diseases. Since 2002, GWASs have successfully identified the genes responsible for complex traits (63). This approach was successfully used to identify the genes associated with serum urate concentrations, a typical quantitative trait. In these studies, the associations between the serum urate concentrations and the genotypes of many single nucleotide polymorphisms (SNPs) (typically the number of SNPs examined is ~500,000) were examined in many subjects (typically more than 10,000 subjects). GWASs have identified many genes associated with urate concentrations in serum, including *SLC22A12*, *SLC22A11*, *SLC2A9*, *ABCG2*, *SLC17A1*, *WDR1*, *GCKR*, *PDZK1*, *R3HDM2-INHBC* region, *RREB1*, and *LRP2* (64–67). Many of these genes code for renal transporters or related proteins, and are thought to be associated with the reabsorption or secretion of urate in the microtubules of the kidney (68–72). These results suggest that many of the genetic factors for hyperuricemia involve the excretion of urate in the kidney rather than its overproduction in the liver.

**95.2.2.5 Treatment.** The typical treatment for acute gouty attacks includes rest, elevation of the affected joint, and administration of a nonsteroidal anti-inflammatory drug (NSAID). Indomethacin is an effective drug, but

other NSAIDs are also effective. NSAIDs are used at the highest approved dose of each selected agent and are usually continued until the pain decreases to a low degree. Orally administered glucocorticoids are as effective as NSAIDs (73). Oral colchicine, given at a dose of, at most, 1.8 mg/day, is also effective in the early stage of an acute gouty attack. However, the administration of colchicine every hour until adverse events occur, such as diarrhea, is no longer recommended. Rather, a small dose of colchicine may be used for the treatment of acute gouty attacks or as a prophylactic drug when patients suffer from frequent attacks and when they have higher probabilities of attacks after urate-lowering drugs are initiated.

If only acute gouty attacks are treated, without any correction of the hyperuricemia, chronic tophaceous gout may develop. In severe cases, destruction of the joints may lead to disability and renal insufficiency may also develop; however, this does not necessarily mean that all patients with hyperuricemia should be treated. Asymptomatic hyperuricemia is not usually the target of urate-lowering therapy, unless the urate concentration is very high. If this is the case, or if the patient has experienced urolithiasis, alkalization of the urine to a pH of ~6.5 (6.2–6.8) by the use of either sodium bicarbonate or potassium sodium citrate is recommended, along with adequate water intake. As the need for a urate-lowering drug is likely to be lifelong, the advantages and the disadvantages of its administration should be carefully compared. The benefits of urate-lowering therapy include the prevention of acute gouty attacks, the inhibition of disease progression to chronic tophaceous gout, and the prevention of the development of urolithiasis and renal insufficiency. The disadvantages include the occurrence of adverse events caused by the drugs and the necessity to attend clinics and hospitals. Urate-lowering therapy should be started when the inflammation of an acute gouty attack has subsided almost completely because the initiation of such therapy during an acute gouty attack almost always leads to the exacerbation and prolongation of inflammation. Three types of urate-lowering drugs are available: uricosuric drugs, xanthine oxidase inhibitors, and uricases. Probenecid and sulfinpyrazone are available uricosuric drugs, and allopurinol and febuxostat (74–77) are available xanthine oxidase inhibitors. Rasburicase (78–80), a recombinant uricase that is used to treat tumor lysis syndrome, prevents or improves the hyperuricemic nephropathy in patients receiving chemotherapy for hematologic neoplasms such as leukemia and lymphoma. Pegloticase (81,82), a pegylated porcine-like uricase that is used by injection, has recently been approved for the treatment of gout in the United States. There is no strict rule as to which type of drug should be used, but pegloticase should only be used in limited cases where its rapid and strong urate-lowering effects are required. Xanthine oxidase inhibitors are recommended for patients with overproduction-type gout or who have experienced episodes of urolithiasis; however,

allopurinol should be avoided or given at lower dosages in patients with renal function impairment because it can cause severe side effects in these cases. In addition, allopurinol-induced severe skin diseases, including Stevens–Johnson syndrome and toxic epidermal necrolysis (TEN), are strongly associated with *HLA-B\*5801*, which is found at a high frequency, especially in patients of Han Chinese ancestry (83).

It is important to note that, even if begun when no inflammation is present, urate-lowering therapy may evoke gouty attacks; therefore, a urate-lowering drug should be started at the lowest effective dose, i.e., 500 mg/day for probenecid, 100 mg/day for allopurinol, and 40 mg/day in the USA, 80 mg/day in Europe, or 10 mg/day in Japan for febuxostat. The dose of each drug should be increased gradually until the serum urate concentration decreases to <6.0 mg/dL or until the highest approved dose is reached. During an initial 6-month period of urate-lowering therapy, acute gouty attacks tend to occur more often than before treatment. Colchicine and an NSAID are used to treat gouty attacks during this period. Prophylactic colchicine coverage is sometimes preferred if gouty attacks are highly expected.

Lifestyle alteration is also an important aspect of urate-lowering therapy. Studies based on a large cohort have shown that alcohol consumption, especially of beer, and high levels of meat and seafood intake are associated with gout (45,46). In addition, weight loss by obese patients has an evident hypouricemic effect. Therefore, change of lifestyle is likely to lower serum urate concentrations. Most large cohort studies have revealed that the serum urate concentration is positively correlated with mortality from ischemic heart disease. However, whether hyperuricemia is an independent risk factor (84–89) or whether the association is secondary to other factors, such as body weight, hyperlipidemia, and hypertension (90–92), is still controversial. Nevertheless, regardless of whether hyperuricemia is an independent risk factor, controlled weight reduction is recommended for obese patients with hyperuricemia because it will prolong their lives.

### 95.2.3 PRPP Synthetase: Superactivity and Deficiency Syndromes

PRPP-synthetase is involved in the synthesis of PRPP, which serves as a cosubstrate for several enzymes involved in the metabolism of purines, pyrimidines, and pyridines. In purine metabolism, PRPP serves as a cosubstrate for amido phosphoribosyltransferase, the first step in the de novo synthesis of purines (Figure 95-1). It also serves as a cosubstrate for the recycling enzymes, HPRT and APRT. In pyrimidine metabolism, PRPP serves as a cosubstrate for uridine monophosphate synthetase (Figure 95-4), which generates the precursor for pyrimidine nucleotide synthesis. Finally, PRPP also is used for the production of the pyridine nucleotides cofactors NAD and NADP. There are three PRPP synthetases encoded

**TABLE 95-1 PRPP Synthetase Disorders**

	PRS1 Superactivity	Arts Syndrome	CMTX5	DFN2
Hearing loss	Variable	Yes	Yes	Yes
Neuropathy	Variable	Yes	Yes	No
Optic atrophy	No	Yes	Yes	No
Psychomotor retardation	Variable	Yes	No	No
Recurrent infections	No	Yes	No	No
Uric acid overproduction	Yes	No	No	No
PRS1 enzyme activity	High	Absent	Low	Low
Reported mutations	D52H, N114S, L129I, D182H, A189V, H192L, H192Q	Q133P, L152P	E43D, M115T	D65N, A87T, I290T, G306R

The reported mutations follow standard nomenclature with one-letter abbreviations to designate the amino acid change.

by three different genes, but only the *PRPS1* gene has been linked with human disease. The mutations affecting the PRS1 enzyme provide an example of how defects in a single gene can lead to four very different clinical phenotypes, which are outlined below and summarized in Table 95-1. For a detailed review, see Reference (93).

**95.2.3.1 PRS1 Superactivity.** Excessively high activity of PRS1 was first described as an X-linked disorder associated with hyperuricemia and gout in young adults (94). Subsequent studies revealed that some patients also suffered from childhood-onset neurological disability characterized by psychomotor retardation and sensorineural hearing loss. The mild form of the disorder with only overproduction of uric acid is thought to reflect misregulation of the gene transcript, because *PRPS1* is overexpressed with no defects in the reading frame. The result is higher PRPP levels, which drive PRPP-dependent enzymes at an unusually high rate. Excessive drive of de novo purine synthesis is the cause of hyperuricemia (93).

The more severe form of the disorder with accompanying neurological defects arises from point mutations in the reading frame for the protein. These mutations result in an enzyme with reduced feedback inhibition, but increased lability. The resulting effect on PRPP levels is complex and probably tissue dependent. Some tissues may have abnormally high PRPP levels, while postmitotic cells such as erythrocytes have low PRPP levels. The mechanisms responsible for the neurological defects are not well understood.

**95.2.3.2 Arts Syndrome.** This syndrome was first described in 1993 as an X-linked disorder with infantile-onset psychomotor retardation, sensorineural hearing loss, and optic atrophy (95). Overproduction of uric acid does not occur. In affected males, death due to recurrent respiratory infections occurred before 5 years of age. The syndrome results from mutations leading to the loss of PRS1 function. The mechanisms for neural dysfunction are not known, and effective treatments are lacking currently.

**95.2.3.3 CMTX5 or Rosenberg–Chutorian Syndrome.** Charcot–Marie–Tooth disease consists of a family of inherited disorders with prominent involvement of peripheral nerves (96,97). It is both clinically and etiologically heterogeneous, with type CMTX5 being caused by mutations in *PRPS1*. Patients with CMTX5 have an

X-linked disorder of peripheral neuropathy combined with sensorineural hearing loss beginning at 10–12 years of age. Overproduction of uric acid does not occur. Mutations causing CMTX5 reduce PRS1 enzyme activity, but do not eliminate it. The mechanisms responsible for neuropathy are not known, but may reflect the heavy dependence of myelin on lipid esters of pyrimidine nucleotides such as CDP-choline, CDP-neuraminic acid, and CDP-ethanolamine.

**95.2.3.4 Progressive Deafness DFN2.** Progressive, nonsyndromic, and postlingual hearing loss type DFN2 also results from point mutations in *PRPS1*. These patients do not have the neurological impairments associated with other *PRPS1* mutations, and they do not overproduce uric acid. The mechanisms for hearing loss are not known (98).

## 95.2.4 Adenylosuccinate Lyase Deficiency

Adenylosuccinate lyase (ADSL, also known as adenylosuccinase) catalyzes two steps in the synthesis of purine nucleotides (see Figure 95-1): the conversion of succinyl-aminoimidazole carboxamide ribotide (SAICAR) into aminoimidazole carboxamide ribotide (AICAR), the eighth step of the de novo pathway, and the formation of AMP from adenylosuccinate (S-AMP), the second step in the conversion of IMP into AMP. ADSL deficiency was the first enzyme defect reported in humans in the de novo pathway of purine synthesis (11). It is mostly characterized by a marked psychomotor delay and the accumulation of succinyl-aminoimidazole carboxamide riboside (SAICA-riboside) and succinyladenosine (S-Ado) in body fluids. These succinylpurines are the products of the dephosphorylation, by 5'-nucleotidase(s), of SAICAR and S-AMP, respectively. This disorder is mainly reported in Europe, probably because of the more intensive screening for this deficiency in European countries than in other areas of the world (99–102).

**95.2.4.1 Clinical Features.** Patients present with variable associations of psychomotor delay, epilepsy, autistic features, hypotonia, and secondary feeding problems. In the first reported presentation, often referred to as type I, patients display moderate-to-severe psychomotor

delay, frequently accompanied by epilepsy after the first years, and various behavior disturbances. In one of these families, severe growth retardation with muscular wasting was also observed. Rare patients, referred to as type II, show strikingly less psychomotor delay than type I patients. Other patients have been reported with convulsions starting within the first days to weeks of life (103), while a few patients display only autistic features (104). Fundoscopy, auditory, somatosensory and visual-evoked responses, nerve conduction velocities, and electromyography are normal, even in patients with muscular wasting. Computed tomography and magnetic resonance imaging of the brain often show hypotrophy or hypoplasia of the cerebellum, particularly of the vermis.

**95.2.4.2 Diagnostic Tests.** Diagnosis is based on the presence of SAICA-riboside and S-Ado in urine and cerebrospinal fluid, which are normally nearly undetectable. For systematic screening, a modified Bratton–Marshall test, performed on urine, appears to be the most practical; however, false positive results may be observed in patients who receive antibiotics, particularly sulfonamides (for whose measurement the test was initially devised), or antiepileptic medications. Succinylpurines can also be detected by other techniques, including two-dimensional thin-layer chromatography with staining of imidazole compounds. The final diagnosis requires high performance liquid chromatography (HPLC) with ultraviolet spectral analysis (11) or tandem mass spectrometry.

**95.2.4.3 Biochemical Features.** ADSL catalyzes the nonhydrolytic cleavage of the C–N bond linking the succinate moiety to the nucleotide part of its two substrates, SAICAR and S-AMP, to yield fumarate, and AICAR and AMP, respectively. The reaction is similar to that catalyzed by the urea cycle enzyme argininosuccinate lyase. ADSL is composed of four subunits of ~50 kDa. The human enzyme has been crystallized and its three-dimensional structure has been clarified (PDB ID: 2vol6). Measurements of the activity of ADSL with S-AMP as a substrate show markedly decreased activity down to undetectable activities in the liver and kidneys of all patients investigated. In peripheral blood lymphocytes, ADSL activity is ~40% of normal, while the activity of erythrocyte ADSL is normal in some patients, but decreased in others. As a rule, a partial deficiency of ADSL is measured in cultured fibroblasts.

A comparison of the activities of ADSL with S-AMP and SAICAR as substrates shows that both are lost in parallel to ~30% of normal in fibroblasts from profoundly retarded, type I patients. In contrast, in fibroblasts from a mildly retarded, type II patient, the activity with S-AMP was reduced to 3% of normal, whereas that with SAICAR was 30% of control. These findings provide an explanation for the markedly higher S-Ado/SAICA-riboside ratio in the body fluids of the latter patient.

**95.2.4.4 Pathophysiologic Mechanisms.** It is more likely that the symptoms of ADSL deficiency are due

to the toxic effects of the accumulating succinylpurines rather than impaired purine nucleotide synthesis. Moreover, the observation of generally less severe mental retardation in patients with similar SAICA-riboside levels, but with S-Ado/SAICA-riboside ratios >2, suggests that SAICA-riboside is the offending compound and that S-Ado could protect against its toxic effects.

**95.2.4.5 Molecular Genetics.** The ADSL gene has been mapped to chromosome 22q13.1–13.2 and encodes a protein of 484 amino acids.

Analysis of the first identified family with ADSL deficiency revealed a T to C substitution, resulting in a S438P change (105,106). In accordance with the variability of the clinical symptoms, many mutations including missense single nucleotide changes, nonsense mutations, splicing error mutations, and mutations in the 5'-untranslated region have been reported in apparently unrelated sibships (Adenylosuccinate Lyase Mutation Database, <http://www.icp.ucl.ac.be/adslldb>). The R426H mutation is the most frequently encountered, accounting for approximately one-third of the alleles investigated. Prenatal diagnosis of ADSL deficiency has been performed twice on chorion villi from the mother of a previously diagnosed patient with a C5T mutation on the maternal allele, and a C1185A mutation on the paternal allele (107).

**95.2.4.6 Treatment.** Some therapeutic trials have been performed, including oral supplements of adenine and the oral administration of ribose and uridine, without remarkable effects (108,109).

The prognosis for survival of ADSL-deficient patients is variable. Several of those presenting with early epilepsy have died within the first months of life. In markedly retarded patients, absent or minimal progression of psychomotor development and the persistence of autistic behavior were observed. Mildly impaired patients have reached adult age and are able to work in a protected environment.

## 95.2.5 AICA-Ribosiduria (ATIC Deficiency)

This was the second enzyme defect identified in humans in the de novo pathway of purine synthesis (13). The first patient was a female infant presenting with profound intellectual disability, marked dysmorphic features (prominent forehead and metopic suture, brachycephaly, wide mouth with a thin upper lip, low-set ears, and a prominent clitoris due to a fused labia majora), and congenital blindness. Urine analysis showed a positive Bratton–Marshall test. This led to the identification of the massive excretion of 5-amino-4-imidazolecarboxamide (AICA)-riboside, the dephosphorylated counterpart of AICAR (see Figure 95-1), also termed ZMP. Analysis of the patient's erythrocytes revealed the accumulation of ZMP and the di- and triphosphates ZDP and ZTP, respectively. Incubation of her fibroblasts with AICA-riboside led to the accumulation of AICAR (not observed

in control cells), indicating the impairment of the final steps of de novo purine biosynthesis. An assay of AICAR transformylase/IMP cyclohydrolase (ATIC), the bifunctional enzyme catalyzing the two last steps of the pathway, revealed a profound deficiency of transformylase and a partial deficiency of cyclohydrolase. Sequencing of the *ATIC* gene showed a K426R change in the transformylase region in 1 allele, and a frameshift in the other. A recombinant enzyme carrying the K426R mutation completely lacks AICAR transformylase activity. The discovery of this novel inborn error of purine synthesis reinforces the necessity to perform a Bratton–Marshall test in all cases of unexplained psychomotor delay and/or neurologic symptoms.

## 95.2.6 Myoadenylate Deaminase Deficiency

Adenylate deaminase (AMPD) catalyzes the deamination of AMP into IMP with release of free ammonia. It is one of three enzymes, along with adenylosuccinate synthetase and adenylosuccinate lyase, which forms the purine nucleotide cycle that is proposed to play a role in energy production during periods of high demand. Adenylate deaminase has four isoforms, encoded by three different genes. A muscle-specific form known as myoadenylate deaminase (mAMPD) is encoded by *AMPD1* on chromosome 1. Deficiency of mAMPD was first reported for five patients with exercise-induced cramping and myalgias (12). Later studies revealed mAMPD deficiency in 1–2% of the Caucasian population, most of whom had no symptoms. The large number of asymptomatic patients raised the possibility that the loss of mAMPD is a harmless genetic variant. However, there are three different situations outlined below where mAMPD deficiency may be clinically important. For a detailed review, see (110).

### 95.2.6.1 Primary Myoadenylate Deaminase Deficiency.

**95.2.6.1.1 Clinical Features.** Approximately 200 patients have been reported. Most present in the second to fourth decades of life, with poor exercise tolerance due to cramps or myalgias. Muscle wasting does not occur. Around half exhibit minor increases in serum creatine kinase. Electromyographic abnormalities and overt histological defects suggestive of myopathy usually are absent, although minor abnormalities are sometimes found. Rhabdomyolysis with myoglobinuria occurs only rarely.

**95.2.6.1.2 Pathogenesis.** Symptomatic primary mAMPD deficiency is thought to be inherited as an autosomal recessive disorder due to mutations in *AMPD1*. The majority of symptomatic patients harbor a common homozygous mutation c.34C>T leading to Q12X, which has null activity (111). However, a few other mutations also have been reported.

A causal role for homozygosity of the c.34C>T allele in symptom production has been called into question because this same allele is present in nearly a quarter of

the Caucasian population with 1–2% of the population being homozygous (111,112). Several mechanisms have been proposed to explain the lack of symptoms in this larger population (110). One is that the compensatory mechanisms, such as the upregulation of other AMPD isoforms, may mask symptoms. Another possible mechanism involves alternative splicing. The mutation resides within a miniexon that is alternatively spliced out, leaving a potentially functional variant enzyme. A possible final mechanism is that the mutant allele by itself is not pathogenic, but becomes pathogenic when combined with some other defect.

**95.2.6.1.3 Diagnosis.** Deficiency of mAMPD can be detected by the failure of ammonium production during the ischemic forearm exercise test, which involves inflating a sphygmomanometer cuff around the upper arm to measure arterial pressure. After squeezing the hand manometer for 2 min, the several-fold elevation of venous ammonia seen in normal subjects is absent in affected patients (113). Definitive diagnosis is established by histochemical or biochemical assay of the enzyme from a muscle biopsy specimen. Generally, mAMPD activity is <2% of normal.

### 95.2.6.2 Secondary Myoadenylate Deaminase Deficiency.

**95.2.6.2.1 Clinical Features.** The term “secondary mAMPD deficiency” has been used to describe the reductions in normal *AMPD1* mRNA transcripts and associated mAMPD enzyme activity that have been documented for several clinical disorders (110). This phenomenon has been reported for several neuromuscular disorders such as amyotrophic lateral sclerosis, fascioscapulohumeral myopathy, Kugelberg–Welander syndrome, polyneuropathy, Werdnig–Hoffmann disease, and myophosphorylase deficiency. It also has been reported for some connective tissue disorders. The symptoms of the primary disorder dominate the clinical picture, though synergy with mAMPD deficiency may make the primary disorder appear worse.

**95.2.6.2.2 Pathogenesis.** Most patients with secondary mAMPD deficiency are heterozygous for a mutation in *AMPD1* and transcription from the normal allele is significantly reduced. The mechanisms responsible for the lowered transcript levels are not known. Because *AMPD1* mRNA transcripts are reduced but not absent in secondary mAMPD deficiency, some residual AMPD enzyme activity sometimes can be detected.

**95.2.6.2.3 Diagnosis.** Patients with secondary mAMPD deficiency fail the forearm ischemic exercise test and usually have a negative histochemical reaction for AMPD in muscle biopsies. However, some staining can be observed if incubation times are extended beyond routine measures.

### 95.2.6.3 Coincidental Inherited Myoadenylate Deaminase Deficiency.

**95.2.6.3.1 Clinical Features.** The term “coincidental mAMPD deficiency” has been used to describe the clinical situation wherein homozygous or compound

heterozygous mutations in *AMPD1* are coincidentally found in other neuromuscular or rheumatological disorders (110). The clinical features are dominated by the associated neuromuscular or rheumatological disorder, although they may be worse than usual.

**95.2.6.3.2 Pathogenesis.** The pathogenesis of symptoms in coincidental mAMPD deficiency is heterogeneous, and the exact role for the enzyme deficiency is variable and sometimes uncertain. The term “double trouble” has been used to describe one subset of individuals with metabolic myopathy with complete mAMPD deficiency due to homozygosity for Q12X, along with a second defect in another gene known to cause myopathy (114). These patients may have a more profound phenotype than that observed in either disorder alone. Another subset of individuals has been described where heterozygosity for the Q12X mutation is found along with complete genetic deficiency of other metabolic pathways. Once again, symptoms may be more severe than those typically associated with the isolated metabolic disorder. Finally, the term “synergistic heterozygosity” has been applied to a third subset of individuals who carry heterozygous mutations for more than one step in the same metabolic pathway (115,116). In these patients, the combined partial defects may lead to phenotypes that resemble individuals with more complete deficiencies of the pathways involved.

## 95.2.7 Adenosine Deaminase Deficiency

ADA catalyzes the deamination of adenosine and of its deoxy counterpart deoxyadenosine. A gross deficiency of ADA was first reported by Giblett and coworkers (7) in two unrelated children with profound impairment of cellular (T-cell) and humoral (B-cell) immunity, known as severe combined immunodeficiency disease (SCID). Since that time, several hundred patients with ADA deficiency have been diagnosed. Most cases present soon after birth with a life-threatening susceptibility to infections that, if left untreated, invariably lead to an early death, unless drastic steps are taken such as rearing in strictly sterile conditions from birth onward. The development of bone marrow transplantation, enzyme replacement therapy, and gene therapy has drastically changed the prognosis of ADA deficiency.

**95.2.7.1 Clinical Features.** Symptoms of ADA deficiency vary between patients. The most severe patients present in infancy and usually die early if untreated. Ten to fifteen percent of patients have a “delayed” clinical onset by the age of 6–24 months, and a smaller percentage of patients have a “later” onset, diagnosed from the age of 4 years to adulthood. In addition, “partial” ADA deficiency occurs in apparently healthy individuals who show decreased enzyme activity in erythrocytes, but retain substantial enzyme activity ranging from 5 to 80% of normal in leukocytes and other nucleated cells (117). ADA deficiency is observed in ~15% of all SCID cases and one-third of cases of autosomal recessive SCID. Many

patients show a clinical and radiologic bony abnormality of the thorax, with flaring of the costochondral rib junctions, but this is not a consistent or specific finding. Neurologic abnormalities are found in a few affected children, including spasticity, head lag, movement disorders, and inability to focus. Autoimmunity may occur and hepatic dysfunction has also been reported.

**95.2.7.2 Diagnostic Tests.** ADA deficiency should be suspected in all patients who show recurrent infections during the first year of life. Affected patients display a profound impairment of T-cell function with varying degrees of B-cell dysfunction, which can be evidenced by relatively simple laboratory tests; lymphopenia (usually <500 total lymphocytes/mm<sup>3</sup>) involving B- and T cells, and hypogammaglobulinemia are almost invariably present. Immunoglobulin M deficiency may be detected early, but immunoglobulin G deficiency becomes manifest only after the age of 3 months when the maternal supply has been exhausted. More complex tests show a deficiency of antibody formation following specific immunization and an absence or severe diminution of lymphocyte proliferation induced by mitogens. The disease is progressive because residual B- and T-cell functions, which may be present at birth, disappear later on.

Enzymatic diagnosis of ADA deficiency is mostly performed on red blood cells. In general, disease severity correlates with the loss of ADA activity; in children with neonatal or infant-onset SCID, its residual activity is 0–0.1% of normal, and in subjects with delayed or later onset, 1–5% of control activity is found (118). Only ~15% of patients with the clinical and hematologic picture of inherited SCID are ADA deficient. In the remaining patients, SCID is caused by other mechanisms. In subjects with partial ADA deficiency, the enzyme is deficient in red blood cells, but sufficient residual ADA activity is present in their lymphocytes.

**95.2.7.3 Biochemical Features.** *Properties of Normal and Mutant Enzymes.* ADA is a monomeric enzyme with a molecular weight of ~40 kDa. In several epithelial cell types, it is associated with an ADA-binding cell membrane glycoprotein that seems to play a role in thymocyte proliferation. ADA is present in all cell types, but its activity is highest in the thymus and other lymphoid tissues. The crystal structure of human ADA has been resolved (PDB ID: 3iar).

*Pathophysiologic Mechanisms.* ADA deficiency results in the accumulation of adenosine and deoxyadenosine, the latter derived from DNA catabolism, which are normally nearly undetectable. Several pathogenic mechanisms have been proposed that might act in concert. Inside lymphocytes, excess deoxyadenosine leads to the accumulation of dATP, which is probably the primary lymphotoxic compound in ADA deficiency. Indeed, dATP potently inhibits ribonucleotide reductase, an essential enzyme for the synthesis of DNA and, hence, for lymphocyte development and differentiation. Moreover, dATP has been shown to induce mitochondrial

cytochrome C release, followed by apoptosis in fetal ADA-deficient thymocytes (119,120). On the other hand, deoxyadenosine has been shown to cause the irreversible suicide inactivation of *S*-adenosylhomocysteine hydrolase, an enzyme of the transmethylation pathway. As lymphocyte stimulation has been suggested to require methylation, this inactivation might contribute to the deficiency in lymphocyte function.

**95.2.7.4 Molecular Genetics.** The frequency of the deficiency is estimated at 1 per 100,000–500,000 births. Studies of the *ADA* gene, located on chromosome 20q13.11, have revealed a variety of mutations. Approximately two-third of them are single nucleotide changes, resulting in an inactive or unstable enzyme (121). Missense mutations are distributed throughout the gene, and most arise from codons that contain the CpG dinucleotide. Most patients are compound heterozygotes but others, mainly from consanguineous matings or inbred geographical communities, are homozygous. In recent years, knowledge of the structure of *ADA* and the systematic expression of mutant alleles has revealed that the genotype is an important determinant of the phenotype in *ADA* deficiency, and that the latter is strongly associated with the sum *ADA* activity provided by both alleles (117).

Spontaneous *in vivo* reversion to normal of an inherited mutation in one allele has been reported in a patient with *ADA* deficiency (122).

**95.2.7.5 Treatment.** Treatment of *ADA* deficiency became possible with the advent of bone marrow transplantation. This remains the first choice therapy, provided there is an HLA-identical sibling, HLA-haploidentical parent, or an HLA-matched unrelated donor, and gives a good chance for a complete cure, clinically and immunologically (123). The graft provides stem cells, and hence T- and B cells, which have sufficient *ADA* activity to prevent the accumulation of adenosine and deoxyadenosine. However, survival is much lower with HLA-mismatched transplants (124).

When no histocompatible bone marrow donor is found, enzyme replacement therapy can be used. Effective enzyme replacement therapy is achieved with polyethylene glycol-modified *ADA* (PEG-*ADA*). Covalent attachment of the inert polymer PEG to bovine *ADA* results in a markedly prolonged circulation life and diminished immunogenicity. Weekly to biweekly intramuscular injections of 15–30 U/kg usually results in marked clinical improvements, while *in vitro* immune function also significantly improves (125).

The first approved clinical trial of gene therapy was performed in 1990 in two *ADA*-deficient girls (126). Their peripheral T-cells were collected, cultured with interleukin-2, corrected by the insertion of the *ADA* gene by means of a retroviral vector, and reinfused. Although improvements in their cellular and humoral immune responses were observed (127), the patients continued to receive PEG-*ADA*. This very first attempt showed that the procedure was feasible and safe, and led to the persistence of transduced T-cells for as much as 15–20 years.

From the late 1990s, five different groups began *ex vivo* gene therapy with retroviral vectors using hematopoietic stem cells for SCID-X1 disease and *ADA* deficiency. The immunodeficiency was corrected in 19 of 27 (70%) *ADA*-deficient patients (128–130). Although 5 of 20 patients that received *ex vivo*-transduced autologous hematopoietic stem cells developed T-cell leukemic disease, this genotoxicity was not observed in *ADA*-deficient patients who had been similarly treated (128–130).

## 95.2.8 Adenosine Deaminase Superactivity

A hereditary, ~50-fold elevation of erythrocyte *ADA* has been shown to cause nonspherocytic hemolytic anemia (131). The latter can be explained by the enhanced catabolism of adenine nucleotides, including ATP, owing to the increased activity of *ADA*.

## 95.2.9 Purine Nucleoside Phosphorylase Deficiency

Their discovery of *ADA* deficiency prompted Giblett and colleagues (8) to search for other defects of purine and pyrimidine metabolism in patients with immune disorders. This resulted in the discovery of purine nucleoside phosphorylase (PNP) deficiency in a child with an isolated defect of T-cell function. The disorder is much less frequent than *ADA* deficiency, with 67 patients from 49 families reported to date.

**95.2.9.1 Clinical Features. Presentation.** Recurrent infections are usually of later onset, starting from the end of the first year, up to 5–6 years of age, and are initially less severe than in *ADA* deficiency (121). A strikingly enhanced, life-threatening susceptibility to viral diseases, such as varicella, measles, cytomegalovirus, and vaccinia has been reported, but severe candida and pyogenic infections also occur. One-third of the patients have anemia, while two-thirds display neurologic symptoms, including spastic tetraplegia or diplegia, ataxia, and tremor. Immunologic studies reveal an increasingly severe deficiency of cellular immunity, reflected by a marked reduction in the number of T-cells. B-lymphocyte function can be normal but is deficient in approximately one-third of the patients. Autoimmune disorders are also common, including hemolytic anemia, idiopathic thrombocytopenic purpura, and autoimmune neutropenia.

**Diagnostic Tests.** Patients often display a striking decrease in the production of uric acid; plasma uric acid is usually <1 mg/dL and may even be undetectable. However, in patients with residual PNP activity, uricemia may be at the borderline of normal. The urinary excretion of uric acid is usually also markedly diminished. In contrast, these patients excrete very large amounts of the substrates of PNP: inosine, guanosine, and their deoxy counterparts. Enzymatic diagnosis is mostly performed on red blood cells.

**95.2.9.2 Biochemical Features.** *Properties of normal and mutant enzymes.* Human PNP catalyzes the phosphorolysis of inosine and deoxyinosine, and guanosine and deoxyguanosine into hypoxanthine and guanine, respectively, and ribose-1-phosphate or deoxyribose-1-phosphate. It does not act on adenosine or deoxyadenosine. PNP is active as a 32-kDa monomer, but appears to be a trimer, as confirmed by crystallographic analysis of the human erythrocyte enzyme. Mutant enzymes can be completely inactive or display some residual activity.

*Pathophysiologic Mechanisms.* PNP deficiency provokes an accumulation in body fluids of the four normally nearly undetectable substrates of the enzyme, namely guanosine, inosine (see Figure 95-1), and their deoxy counterparts (not shown in Figure 95-1), the latter are derived from DNA breakdown. Formation of uric acid is thus severely hampered. The profound impairment of cellular immunity that characterizes the disorder has been explained by the greater ability of T-cells as compared with B cells to accumulate dGTP, although other factors also seem to intervene. Formed from deoxyguanosine, dGTP inhibits ribonucleotide reductase, and hence, cell division. As observed for dATP in ADA deficiency, dGTP also probably provokes apoptosis in PNP-deficient lymphocytes.

**95.2.9.3 Molecular Genetics.** PNP deficiency is inherited in an autosomal recessive fashion. Studies of the *PNP* gene, located on chromosome 14q13, have revealed a number of molecular defects, among which an R234P mutation is the most common (132). Genotype–phenotype correlations are hampered by the diversity of mutations and small number of patients.

**95.2.9.4 Treatment.** Most initially diagnosed patients have died from overwhelming viral or bacterial infections, although at a later age than untreated ADA-deficient children. The treatment consisted of bone marrow transplantation and repeated transfusions of normal, irradiated erythrocytes. More recently, successfully matched bone marrow transplantation has been reported (133–135), although without an improvement of the neurologic symptoms (136).

## 95.2.10 Xanthine Oxidase Deficiency

Xanthine oxidase is also termed xanthine dehydrogenase or xanthine oxidoreductase (XOR). XOR deficiency is characterized by xanthinuria, and was the first enzyme defect reported in human purine metabolism (9). Originally described as a benign disorder, it was subsequently found that it could also occur in combination with defects of two other molybdenum-requiring enzymes: aldehyde oxidase and sulfite oxidase (10). Three types of XOR deficiency are now recognized: (a) type I, isolated XOR deficiency; (b) type II, combined XOR and aldehyde oxidase deficiency, which causes equally benign xanthinuria; and (c) combined deficiency of XOR, aldehyde, and sulfite oxidase, which, in contrast to the other two types, provokes a devastating disorder similar to isolated sulfite

oxidase deficiency. It is caused by the failure to synthesize the molybdenum cofactor common to the three oxidases.

**95.2.10.1 Clinical Features.** *Presentation.* Type I and type II XOR deficiency can be completely asymptomatic, although kidney stones are formed in approximately one-third of the cases. Although these are most often not visible on a radiograph, they may appear at any age and cause a variety of symptoms including hematuria, renal colic, and even acute renal failure. Myopathy may be present, precipitated by strenuous exercise and associated with crystalline xanthine deposits in muscle. In combined XOR and sulfite oxidase deficiency, the clinical picture of sulfite oxidase deficiency, which is also found as an isolated defect (137), overrides that of XOR deficiency. The symptoms include neonatal feeding difficulties and intractable seizures, myoclonus, increased or decreased muscle tone, eye lens dislocation, and severe intellectual disability.

*Diagnostic Tests.* In isolated and combined XOR deficiency, <1 mg/dL plasma concentrations of uric acid are detected; they may decrease to virtually undetectable values on a low-purine diet. Urinary uric acid is reduced to a few percent of normal and is replaced by hypoxanthine and xanthine. In combined XOR and aldehyde oxidase deficiency (xanthinuria type II), patients are unable to oxidize allopurinol. In combined XOR, aldehyde, and sulfite oxidase deficiency, the urinary changes of xanthinuria are accompanied by the excessive excretion of sulfite and other sulfur-containing metabolites, e.g., S-sulfocysteine, thiosulfate, and taurine. Enzymatic diagnosis requires liver or small intestine mucosa that normally contains substantial amounts of xanthine oxidase. Sulfite oxidase and the molybdenum cofactor can be assayed in the liver and fibroblasts.

**95.2.10.2 Biochemical Features.** XOR is a homodimer composed of two subunits of ~150 kDa. Each subunit contains a molybdenum center, which contains molybdenum under the form of a molybdenum cofactor, similar in structure to that of several other molybdoenzymes. Mutant XOR has been investigated in a few patients. Despite unmeasurably low activity, immunoreactive protein remains detectable in the duodenal mucosa of some patients, but not of others (138).

*Pathophysiologic Mechanisms.* XOR deficiency results in the near-total replacement of uric acid by hypoxanthine and xanthine as the end products of purine catabolism (see Figure 95-1). This alteration is clearly detectable in urine, in which >90% of oxypurine excretion is normally uric acid. Plasma hypoxanthine levels are, as a rule, not or minimally elevated in various forms of XOR deficiency, owing to its efficient reutilization by HGPRT. Plasma xanthine, normally <1  $\mu$ M, may rise to 10–40  $\mu$ M, which is far below the normal uric acid level because of the markedly higher renal clearance of xanthine.

Concentrations of hypoxanthine and xanthine are ~10-fold higher than normal in the muscle of xanthinuric subjects. The limited solubility of xanthine may explain the observation of numerous birefringent crystals in the

muscles of patients complaining of pain and stiffness. The role of hypoxanthine, which increases during vigorous exercise in normal and xanthinuric subjects, is unclear because it is much more soluble than xanthine.

**95.2.10.3 Molecular Genetics.** The inheritance of type I and type II XOR deficiency and of combined XOR and sulfite oxidase deficiency is autosomal recessive. Studies of the XOR gene, localized on chromosome 2p22, have led to the identification of two mutations in hereditary xanthinuria type I: a nonsense substitution and a termination codon (138). Xanthinuria type II is caused by mutations of the molybdenum cofactor sulfurase gene (139,140). In patients with molybdenum cofactor deficiency, mutations have been found in three genes: *MOCS1* (type A deficiency), *MOCS2* (type B deficiency), and *GPHN* (only 1 case has been reported) (141–143). The products of these three genes are considered necessary for the synthesis of the molybdenum cofactor.

**95.2.10.4 Treatment.** Isolated XOR deficiency is mostly benign, and a low-purine diet should be prescribed and fluid intake increased. However, the prognosis of combined XOR and sulfite oxidase deficiency is very poor. So far, all therapeutic attempts, including low-sulfur diets, the administration of sulfate and molybdenum, and trials to bind sulfite with thiol-containing drugs, have been unsuccessful. Veldman et al. reported that cyclic pyranopterin monophosphate supplementation was effective for molybdenum cofactor deficiency type A (144).

### 95.2.11 Hypoxanthine-Guanine Phosphoribosyltransferase Deficiency

Lesch and Nyhan first reported a classical phenotype that now is known as Lesch–Nyhan disease (LND) in 1964 (29). They described two brothers with marked overproduction of uric acid, a motor disorder resembling cerebral palsy, intellectual disability, and a peculiar behavioral syndrome with severe self-injurious behavior. Three years later, Seegmiller and colleagues found deficiency of the purine salvage enzyme, HPRT as the cause (145). Following discovery of the enzymatic basis, there was increasing recognition of milder phenotypes where some of the classical features of LND were absent or unusually mild (145–147). These patients now are known as Lesch–Nyhan variants (LNV). LND and its variants are inherited in an X-linked recessive manner, with nearly all cases being males. The *HPRT1* gene encoding the enzyme was among the first genes to be cloned for any human disease (148), and it is one of the most intensively studied loci in human genetics (149).

**95.2.11.1 Clinical Features.** *Presentation.* The presentation and clinical features of classical LND are quite stereotyped (150–155). Few abnormalities are identifiable during the early neonatal period, but signs of motor

delay become evident within 2–6 months of age. Between 9 months and 4 years of age, involuntary movements become apparent, with increased muscle tone, spasms, and flailing movements. Many LND patients are initially incorrectly suspected of having cerebral palsy, because the presentation and evolution of early motor abnormalities are quite similar. Although motor delay is the presenting feature for the majority of patients, a few may present instead with other problems as infants. Included are complications of uric acid overproduction such as kidney stones or renal failure.

The presentation and clinical features of LNV are more variable (145,154,156). The most severely affected present in a manner similar to LND. Less severely affected LNV patients may present with poor motor skills although a higher proportion present instead with complications from overproduction of uric acid, such as kidney stones or gout during childhood or early adulthood.

*Uric Acid Overproduction.* Overproduction of uric acid is universal in LND and its variants (Figure 95-2). Uric acid is produced at three to five times of normal rates (157). Elevated serum uric acid levels are nearly universal, although the degree of hyperuricemia may be sufficiently small that it escapes notice (158). In rare cases, the serum uric acid may be normal. The reason serum uric acid may be normal or only slightly elevated despite enormous overproduction involves the remarkable ability of the kidneys to clear it from the blood into the urine.

The many renal complications in LND and its variants are related to the massive amounts of uric acid being filtered by the kidneys into the urine (159–162). A common problem is nephrolithiasis with either large kidney stones or sandy sludge-like material that can develop in any portion of the urogenital system. These may result in flank pain, hematuria, obstructive nephropathy, interstitial nephritis, recurrent urinary infections, and renal failure.

Gout also is a complication of uric acid overproduction. Joint pain due to the inflammatory effects of uric acid precipitation in the joints is most common in the feet and hands, but other joints may be involved. If untreated, tophaceous deposits may accumulate, leading to progressive destruction of the joints.

*Behavioral Abnormalities.* Patients with classic LND have a characteristic behavioral phenotype (163–165). Virtually all patients exhibit severe and recurrent attempts to hurt themselves. This behavior most often emerges between 2 and 4 years of age, although it may be delayed until early adulthood. The most common manifestation involves self-biting. Patients commonly bite their fingers and hands, or they may bite their lips, tongue, and cheeks. Other frequent manifestations include self-hitting, banging the arms or legs on nearby hard objects, head banging, eye gouging, or picking and scratching. Over time, it is not uncommon for individual patients to exhibit multiple different forms of self-injury. Self-injury is not due to loss of sensation or to a need for self-stimulation. Patients

**FIGURE 95-2** Schematic representation of the continuous spectrum of clinical features across LND and its variants. The main clinical problems are listed across the top. Patients are subdivided into three typical groups along the left side. The most severely affected group is LND. The least severely affected group is designated HPRT-related hyperuricemia (HRH). An intermediate phenotype is designated HPRT-related neurological dysfunction (HND). The frequency and severity of each of the clinical problems is depicted by the thickness and taper of the gray bar.

report that they do not wish to hurt themselves, but they are unable to stop.

In addition to self-injury, other difficult behaviors are frequent in LND (164,165). These include attempts at hitting others, spitting toward others, or the use of foul or sexually inappropriate language. These behaviors do not appear to be accompanied by aggressive intent, since patients frequently apologize after the behavior and seem embarrassed by it. Instead, the behaviors may be impulsive or compulsive. Oppositional defiant behavior also is frequent. Although the behavioral phenotype might be expected to lead to poor social relationships, patients with LND are often well liked by their families and associated caregivers because they have very engaging personalities.

Patients with LNV do not exhibit self-injurious behavior or overt problem behaviors seen in classical LND. However, impulsivity and oppositional behavior are not uncommon (Figure 95-2) (156,164).

**Motor Disorder.** The motor disorder of classical LND reflects a combination of problems similar to those seen in dyskinetic cerebral palsy (Figure 95-3) (150,151). All patients have severe generalized dystonia with limited practical use of their limbs. Opisthotonic truncal spasms are common. Dysarthria is severe, although patients usually can make themselves understood to those who know them well. Approximately one-third have superimposed choreoathetosis or ballismus. Approximately one-quarter have corticospinal signs such as spasticity, increased muscle stretch reflexes, or clonus. The motor syndrome is established within the first few years of life. It is not relentlessly progressive.

The motor disorder of LNV is more variable (156). The most severely affected LNV patients lack the hallmark behavioral features of LND, but they have a motor

syndrome indistinguishable from classical LND. Moderately affected patients have less disabling dystonia, such that ambulation and self-care may be possible. Less severely affected patients have clumsy motor skills. The least severely affected have normal motor skills.

**Cognitive Abnormalities.** Intellectual disability is nearly universal in classic LND (166–168). Patients sometimes are incorrectly thought to have more severe cognitive impairments because of their difficulties with verbal and other communication, their difficult behaviors, and the limited educational opportunities available to them. However, formal neuropsychological testing typically reveals only mild or moderate intellectual disability, with global IQ scores in the 60–80 range. Intellectual disability also is very common in LNV, although it is less severe than in LND.

**Other Abnormalities.** A variety of other clinical features may also occur in LND and LNV. Feeding difficulties are severe enough to require chronic gastrostomy in approximately a third of those with LND and a few with LNV (151). Many are small for age, and puberty often is delayed. Macrocytic anemia occurs in approximately half of the patients with LND or LNV (169,170). Laryngospasm may cause stridor or recurrent apneas, sometimes severe enough to cause loss of consciousness or even death (171).

**95.2.11.2 Diagnosis. Uric Acid.** The overproduction of uric acid leads to a convenient screening test for LND and its variants, because serum uric acid very frequently is elevated (158). Although hyperuricemia is common, some patients have normal serum uric acid due to high renal clearance. The 24-hour urinary uric acid provides a more sensitive measure, especially when corrected for patient mass by examining the uric acid to creatinine ratio. However, such tests rarely are used for clinical

**FIGURE 95-3** Summary of the motor disorder of LND (gray bars,  $n = 44$ ) and LNV (black bars,  $n = 46$ ) taken from two large studies (151,156). Extrapyramidal (A) and pyramidal (B) features are shown separately.

diagnosis because complete specimens are notoriously difficult to collect.

In addition to the limitations of sensitivity, elevated serum or urinary uric acid is not specific for LND or its variants. Several other disorders may also be associated with hyperuricemia or uricosuria, sometimes reaching or exceeding levels associated with LND or LNV. Thus, evidence for the overproduction of uric acid is helpful as a screening test, but it is not adequate for definitive diagnosis.

**Genetic Testing.** Today, the most widely used method for definitive diagnosis involves documenting a pathological mutation in the *HPRT1* gene (172,173). Mutations are heterogeneous, with more than 400 reported mutations, so sequencing is required. Because mutations are so heterogeneous and often unique, genetic testing often has limited prognostic value for distinguishing among severe or mild phenotypes.

**Enzyme Testing.** Another convenient method for diagnosis involves biochemical measurement of HPRT enzyme activity. Erythrocyte lysates provide a convenient source material for testing, although false negatives and false positives may occur when assays are conducted with artificially high substrate levels (173,174). A more accurate result can be achieved by testing live erythrocytes or fibroblasts with conditions that more faithfully replicate the natural conditions of the enzyme in situ (175–177). There is a rough correlation between the severity of the clinical phenotype and residual enzyme activity, so enzyme testing has some prognostic value (176,177). In classical LND, the live cell assays typically reveal nondetectable enzyme levels. In LNV, some residual enzyme activity usually can be detected. LNV patients with 2–8% activity typically suffer from overproduction of uric

acid with at least some neuromotor dysfunction and/or intellectual disability. LNV patients with more than 8% activity still suffer from overproduction of uric acid, but motor and intellectual functions may appear grossly normal.

**Carrier and Prenatal Diagnosis.** Genetic and enzyme tests both can be used for the detection of asymptomatic female carriers and prenatal diagnosis, although genetic testing is more convenient (178–181). The usual approach is to define the mutation in the affected proband, and then search for the same mutation in others at risk.

**95.2.11.3 Pathogenesis. Molecular Genetic Pathogenesis.** The normal human *HPRT1* gene has nine exons spanning ~45 kb on the long arm of the X-chromosome at Xq26-q27 (149). Because it is on the X-chromosome, males have one copy of the gene but females have two. However, the *HPRT1* gene on the inactivated X-chromosome is transcriptionally silenced by methylation of its CpG clusters, so females also have only one functional copy of the gene.

The mutations responsible for LND and LNV are heterogeneous. As of this writing, more than 400 mutations have been reported (Table 95-1), and new ones are reported yearly. The reported mutations are listed individually at [www.lesch-nyhan.org](http://www.lesch-nyhan.org) (172,173). Approximately, two-thirds of the mutations are single-base substitutions leading to the substitution of a single amino acid, one-quarter are deletions, and the remainder are splice defects, duplications, substitutions, and more complex rearrangements.

Although there is no obvious correlation between individual mutations and specific clinical features, there is a good correlation for the predicted effect of the mutation on HPRT enzyme activity and overall clinical severity

(172,173). The severe LND phenotype typically results from mutations predicted to cause null HPRT enzyme activity such as nonsense mutations, deletions, and other frame-shifting mutations. The milder variants almost invariably occur with single-base substitutions leading to single amino acid substitutions that may permit some degree of residual enzyme activity.

The functional effect of single amino acid substitutions is more difficult to predict. Although early studies suggested that nonconservative amino acid substitutions at the catalytically active site of the enzyme would have the most profound effect on enzyme activity, subsequent studies have demonstrated that mutations outside the active site may have an equally deleterious effect by interfering with protein dimerization, conformational changes required for enzyme action, or protein stability (174,182).

LND and LNV are inherited in an X-linked recessive manner, so virtually all cases are males. However, the classical LND phenotype has been reported for several females (183). All female cases reported to date have had a mutation of one *HPRT1* allele combined with non-random X-inactivation eliminating transcription from the normal *HPRT1* allele, leading to severe enzyme deficiency (172,183).

**Biochemical Pathogenesis.** The *HPRT1* gene encodes a protein of 219 amino acids with a mass of 25 kDa (158). The gene is expressed in all cells of the body at all developmental stages. The HPRT enzyme functions as a dimer or tetramer, and the three-dimensional structure has been resolved by X-ray crystallography from a number of different sources (184–187). HPRT requires magnesium and is one of a small family of enzymes that uses the high-energy bonds of PRPP rather than ATP during catalysis. HPRT is a bifunctional enzyme that converts hypoxanthine to IMP and guanine to GMP.

Mutations resulting in null enzyme activity may cause the deletion of amino acid sequences, early protein truncation, or frame-shifting mutations that yield incorrect amino acid sequences. The effect of point mutations is varied. Biochemical kinetic studies and molecular modeling have suggested that reductions in HPRT activity can be caused by alterations in its kinetic properties toward hypoxanthine, guanine, or PRPP. Other point mutations may disrupt the dimer interface where interactions are required for catalytic activity or protein stability (174,182).

**Pathogenesis of Uric Acid Overproduction.** The pathogenesis of the overproduction of uric acid and its consequences are well understood. First, the absence of HPRT-mediated recycling of hypoxanthine and guanine means that these two bases cannot be reincorporated into the purine pools (188). Both ultimately are catabolized and excreted as uric acid. Second, the synthesis of purines via the de novo pathway is markedly accelerated in the absence of HPRT (157). The mechanism involves accumulation of the PRPP, which serves as a

cosubstrate for both HPRT and the rate-limiting step in the de novo pathway, PRPP-glutamine amidotransferase. When HPRT is missing, the accumulating PRPP drives the de novo pathway at an unusually high rate. Thus, the excessive production of uric acid reflects excessive endogenous purine synthesis together with a failure to recycle hypoxanthine and guanine.

The pathogenesis of the complications of overproduction of uric acid is directly related to its relatively low solubility. Uric acid is near its physiological limit of solubility in the body, and chronic elevations increase its risk of precipitation. One common site of precipitation is the synovial fluids of the joints, which cause an inflammatory reaction and the pain known as gout. A persistent elevation of uric acid leads to macroscopic accumulations known as tophi, which may destroy joints. Tophi may also form subcutaneously outside the joints. Other common sites of precipitation are the kidneys and the urogenital systems, due to constant filtration of serum uric acid into the urinary collecting system. Precipitation of small crystals leads to sludge and sandy material in the urine, or larger kidney stones that may occupy the entire renal medullary collecting system as staghorn calculi.

**Pathogenesis of Neurobehavioral Dysfunction.** The pathogenesis of the neurological and behavioral abnormalities associated with HPRT deficiency is incompletely understood. Many hypotheses have been presented and tested. The earliest focused on the accumulation of some metabolite with putative toxic functions in the nervous system such as uric acid, oxypurines, or PRPP (158). However, there is no experimental evidence for toxicity of any such metabolite. Additionally, there is no evidence for any neurodegenerative process that might be expected from neurotoxicity. Other hypotheses focused on a putative deficiency of the products of HPRT such as IMP or GMP, or more likely their phosphorylated derivatives, such as ATP or GTP (158). Once again, there has been no experimental evidence for deficiency of any such purine metabolites in the brain.

Although the purine metabolic pathways responsible for the neurobehavioral features are not well understood, there is a much better understanding of the brain pathways that are involved. Dysfunction of the basal ganglia, and particularly its dopaminergic connections, has been postulated to be chiefly responsible for the major clinical features including self-injurious behavior, the motor disorder, and intellectual disability (189). Histopathological studies of autopsied brains are largely unrevealing (151,190), although biochemical studies have revealed enormous loss of dopamine in all subregions of the basal ganglia (191–193). Routine clinical neuroimaging studies such as CT and MRI show only minor brain changes (151,194), but PET studies have revealed significant loss of dopamine uptake transporters and the uptake of the dopamine precursor fluoroDOPA (195,196). Detailed studies of a

mouse carrying a deletion mutation of the *HPRT1* gene have similarly revealed significant loss of dopamine and associated markers in the basal ganglia (197,198). *In vitro* tissue culture models based on dopamine neuron-like cells have shown a similar reduction of dopamine and associated markers when HPRT is lost (199–201). All together, these studies have provided strong converging evidence that the loss of HPRT leads to serious dysfunction of dopaminergic neurons. The mechanism by which HPRT deficiency leads to problems in dopamine neurons remains uncertain, but appears to be a metabolic phenomenon rather than a neurodegenerative one (198,202). While the abnormalities of basal ganglia dopamine pathways may be major contributors to the neurobehavioral syndrome of LND and its variants, they do not exclude the possible contributions of other brain regions, such as the corticospinal pathways.

**95.2.11.4 Treatment. Control of Uric Acid.** It is essential to control the excessive production of uric acid to avoid the complications of kidney stones and gout. Effective control requires two ingredients. The first is the use of an inhibitor of xanthine oxidase to suppress the production of uric acid. Allopurinol is used in most cases, although febuxostat also may be used. The second ingredient for managing the overproduction of uric acid is generous hydration at all times, and especially during periods of excess water loss such as particularly hot days, febrile illnesses, or protracted vomiting or diarrhea. The purpose of hydration is to ensure adequate flushing of uric acid and its precursors from the kidneys and through the urogenital system.

Despite vigilant treatment, some patients may still develop kidney stones. In some cases, these may be due to medication noncompliance or inadequate doses of allopurinol leading to uric acid stones. In other cases, recurrent stones may be due to inadequate hydration or overaggressive lowering of uric acid levels, which increases the risk of stones composed of the uric acid precursors, xanthine and hypoxanthine (203). Chemical analysis of the composition of the stones can be helpful in determining the reasons for recurrent stone development and for creating a strategy for stopping it.

**Control of Behavioral Problems.** There are no simple and effective treatments for the self-injurious behaviors. Self-injury is managed by a combination of medications, behavioral interventions, and physical protective devices. There are no oral medications with guaranteed efficacy against self-injurious behaviors, but some may provide at least partial benefits. These include benzodiazepines, gabapentin, and in some cases neuroleptics (163,204,205). Many other medications have been tested with no obvious benefit including serotonin reuptake inhibitors, opiate antagonists, carbamazepine, and levodopa (158). Behavioral interventions emphasize on positive reinforcement of good behaviors and extinguish bad ones through a systematic process of ignoring them, within the limits of safety (206). Negative reinforcement through punishment

sometimes has a paradoxical negative effect of worsening the target behaviors, so this approach is avoided (207). The most effective means for controlling self-injury involves the use of physical protective devices. Self-hitting or biting the fingers and hands can be prevented by straps that limit arm movement, elbow splints that prevent flexing the arm toward the face, or mittens over the hands. The feet and legs may be similarly protected.

The control of self-biting is more difficult when it involves the lips, tongue, or cheeks. Here, the only reliable solution is dental extraction. Many families and providers are reluctant to remove teeth due to permanent disfigurement. However, the consequences of permanent disfigurement from self-biting can be worse, and most families are very relieved when the possibility of self-biting is eliminated by dental extraction. Ultimately, more than half of patients with classic LND have most or all of their teeth removed. When biting begins, lengthy titration periods of oral medications, and lengthy attempts at behavioral intervention are discouraged, because self-biting may be rapid and aggressive, leading to permanent disfigurement in a few minutes or hours.

**Minimizing Motor Disability.** There are no treatments that are fully effective against the motor disability. Medications commonly used to reduce muscle tone include benzodiazepines and baclofen. Assistive devices such as a wheelchair are essential for reducing the impact of motor disability. Wheelchairs often must be customized, so that all sharp or hard objects within reach are covered by soft padding to avoid self-injury.

**Experimental Therapies.** Bone marrow transplantation has been performed for several patients with LND. None of them were benefitted, and the majority died prematurely as a result of complications of the procedure or subsequent immunosuppressive therapy (208,209). The lack of benefit is not surprising, because there is no obvious mechanism whereby the restoration of HPRT enzyme activity in bone marrow can correct the enzyme defect in brain neurons during the developmental period when it is most needed (210). Because of the lack of a rational mechanism together with the unusually high mortality, bone marrow transplantation should not be offered to patients with LND.

Deep brain stimulation also has been performed for several patients with LND (211–214). This technique involves installing an electrode deep into the brain in the region of the globus pallidus, and providing chronic electrical stimulation via an implantable impulse generator. It has proven useful for the treatment of several movement disorders, including Parkinson's disease, tremor, and dystonia. The technique has been reported to reduce the severity of dystonia in LND and suppress self-injury too. However, the results seem to vary from one patient to the next, with dramatic benefits in some and little or no benefits in others. This method seems promising, but further studies are needed to determine the optimal location for stimulation and the optimal stimulation parameters.

### 95.2.12 Adenine Phosphoribosyltransferase Deficiency

Adenine phosphoribosyltransferase (APRT) catalyzes the salvage of adenine into AMP, using PRPP as cosubstrate (see Figure 95-1). Its deficiency was first identified in heterozygotes with partial enzyme deficiency (4). Later, Cartier and Hamet (5) described a 4-year-old child with urinary crystals and stones. These were produced by the conversion of adenine, in the absence of other metabolic routes, into 2,8-dihydroxyadenine (2,8-DHA) by xanthine oxidase. Symptoms are caused by the very poor solubility of 2,8-DHA. More than 300 patients have been diagnosed worldwide, but up to 50% of APRT-deficient subjects may be asymptomatic.

**95.2.12.1 Clinical Features.** *Presentation.* The deficiency may become clinically manifest in childhood, even from birth, but it may also remain silent for several decades. Symptoms include the urinary passage of gravel, small stones, and crystals, frequently accompanied by abdominal colic, dysuria, hematuria, and urinary tract infections. Some patients may present with acute anuric renal failure, whereas others have developed chronic renal failure requiring dialysis and transplantation. The urinary precipitates are composed of 2,8-DHA and are radiolucent.

*Diagnostic Tests.* The observation of brownish spots on diapers or the finding of round, brownish crystals in urine under a light microscope suggest the presence of 2,8-DHA. Notwithstanding its very low solubility, 2,8-DHA can also be identified by HPLC. Confirmation of its presence requires complex analyses, including ultraviolet and infrared spectrography, mass spectrometry, X-ray crystallography, and capillary electrophoresis; therefore, it is usually easier to measure APRT activity. On the basis of the level of residual enzyme activity in red blood cell lysates, two types of APRT deficiency are recognized (see later). In both types, APRT activity is absent in intact cells.

**95.2.12.2 Biochemical Features.** APRT deficiency results in the suppression of adenine salvage (see Figure 95-1), provided by food and the polyamine pathway (not shown in Figure 95-1). Consequently, adenine is oxidized by xanthine oxidase into 2,8-DHA. This compound has solubility in urine, at pH 5 and 37°C, of ~0.3 mg/dL, which is far below that of uric acid.

Human APRT is a dimer with a molecular weight of ~38 kDa. In addition to adenine, many pharmacologic adenine analogs are substrates for APRT, which therefore plays an important role in their conversion into active compounds.

Patients with type I APRT deficiency have no detectable activity in erythrocyte lysates. In patients with type II deficiency, significant residual activity is found, reaching 5–25% of normal when measurements are made at supraphysiologic, saturating concentrations of PRPP. However, kinetic studies reveal that the  $S_{0.5}$  value for PRPP, which is ~3  $\mu$ M for the normal enzyme, is increased to 50–80  $\mu$ M.

This decreased affinity for PRPP results in its near inactivity under physiologic conditions; consequently, APRT activity is not detectable in intact cells such as erythrocytes or fibroblasts. Confirmatory diagnosis of type II deficiency is performed on viable T-cells (215). To date, type II patients have only been found in Japan, where they account for ~80% of the affected subjects.

**95.2.12.3 Molecular Genetics.** The human APRT gene has been mapped to chromosome 16q24.3. In Caucasian and Japanese subjects, a number of polymorphisms are observed. In type I deficiency, >30 mutations have been identified, where ~50% of these are single-base changes. The observation of a number of more common mutations suggests founder effects. All of the type II Japanese patients carry the same T2069C substitution in exon 5, resulting in an M136T change. Approximately 80% of patients are homozygous. Another nonsense mutation, W98X, and a CCGA insertion resulting in a frameshift, account for nearly all of the other cases (216).

Recently, the 3-dimensional structure of human APRT has been determined at 2.1 Å resolution (217). This has provided insights into the mechanisms by which a number of mutations hamper the enzyme's normal activity.

**95.2.12.4 Treatment.** In patients with symptoms, allopurinol should be given, as detailed under "Treatment of Gout," to inhibit the formation of 2,8-DHA. In patients with stones and in those without symptoms, dietary purine restriction and high fluid intake are recommended. Alkalinization of the urine is, however, not advised; unlike that of uric acid, the solubility of 2,8-DHA does not increase up to pH 9. Shock-wave lithotripsy has been beneficial in a small number of patients.

The ultimate prognosis depends on the patient's renal function at the time of diagnosis; late recognition may result in irreversible renal insufficiency that requires chronic dialysis, and early treatment may result in the prevention of stones. Kidney transplantation is sometimes necessary because of severe renal damage (218,219); however, the recurrence of microcrystalline deposits and the subsequent loss of graft function should be prevented with allopurinol. Although a theoretical alternative to allopurinol is febuxostat (72), there have been no reports of the treatment of an APRT-deficient patient with that drug.

### 95.2.13 Thiopurine Methyltransferase Deficiency

Thiopurine S-methyltransferase (TPMT) catalyzes the S-methylation of a number of synthetic purine analogs that contain a thiol group, e.g., 6-mercaptopurine, 6-thioguanine, and azathioprine, which is converted to 6-mercaptopurine in vivo. These drugs are currently used to treat a variety of diseases, including cancer, rheumatoid arthritis, and other autoimmune disorders, and also as immunosuppressants after organ transplantation. The thiopurines are converted through

phosphoribosylation by HGPRT and APRT into active thionucleotides, which exert their therapeutic action by being incorporated into DNA and RNA. Their oxidation by xanthine oxidase, and S-methylation by TPMT, results in their inactivation.

The wide variation in the therapeutic response and occurrence of toxic side effects in individual patients receiving thiopurines led to the identification of TPMT as a determining factor in this variability (14,31). The frequency of variant *TPMT* alleles differs between different ethnic groups; thus, Collie-Duguid et al. found that the frequency of individuals with a *TPMT* variant was 10% (20 of 199) in Caucasians, 2% (2 of 99) in South-west Asians, and 4.7% (9 of 192) in Chinese (220). The composition of the variant alleles also differs between different ethnic groups; thus, *TPMT*\*3A (A154T and Y240C) is the most frequent variant allele among Caucasians, while *TPMT*\*3C (R215H) is the most frequent among Japanese and Chinese patients (220).

The determination of TPMT status before treatment with thiopurines is therefore now recommended and considered one of the best examples of predictive pharmacogenetics (221–223); however, it is not clear whether the enzyme assay or genotyping is preferred (224,225).

#### 95.2.14 Deoxyguanosine Kinase Deficiency

Homozygosity mapping was used to identify the causative gene in three large consanguineous kindreds of Druze origin with the hepatocerebral form of mitochondrial DNA depletion syndrome, characterized by early progressive liver failure, neurologic abnormalities, hypoglycemia, and increased lactate (15). This analysis led to the identification of a deficiency in mitochondrial deoxyguanosine kinase. This enzyme phosphorylates the deoxy counterpart of guanosine (see Figure 95-1) into deoxyGMP. Its deficiency results in an imbalance in the supply of mitochondrial DNA precursors, particularly in the liver and brain that lack a cytosolic form of this enzyme. A single nucleotide deletion (204delA) in the mitochondrial deoxyguanosine kinase gene segregated with the disease in 19 patients from the 3 kindreds (15). Since then, various mutations have been reported. This enzyme deficiency may be frequent since deoxyguanosine kinase gene mutations were found by postmortem search in 4 (14%) of 28 infants with severe progressive liver failure of unknown cause: two homozygotes, one compound heterozygote, and one heterozygote (226).

### 95.3 PYRIMIDINE METABOLISM

#### 95.3.1 Metabolic Pathways

As in the purine nucleotides, the metabolism of the pyrimidine nucleotides can be divided into three pathways (see Figure 95-4):

The biosynthetic pathway, also often termed *de novo* pathway, starts with the formation of the high-energy

compound, carbamoyl phosphate, by cytosolic carbamoyl phosphate synthetase (CPS II). This enzyme is different from mitochondrial CPS I, which catalyzes the first step of ureogenesis. The formation of carbamoyl phosphate is followed by the synthesis of UMP, CMP, their deoxy counterparts, and TMP.

The pyrimidine catabolic pathway starts from (deoxy)CMP, (deoxy)UMP, and TMP. (Deoxy)uridine and thymidine are degraded to finally  $\beta$ -alanine and  $\beta$ -aminoisobutyrate, respectively, which are converted into intermediates of the citric acid cycle.

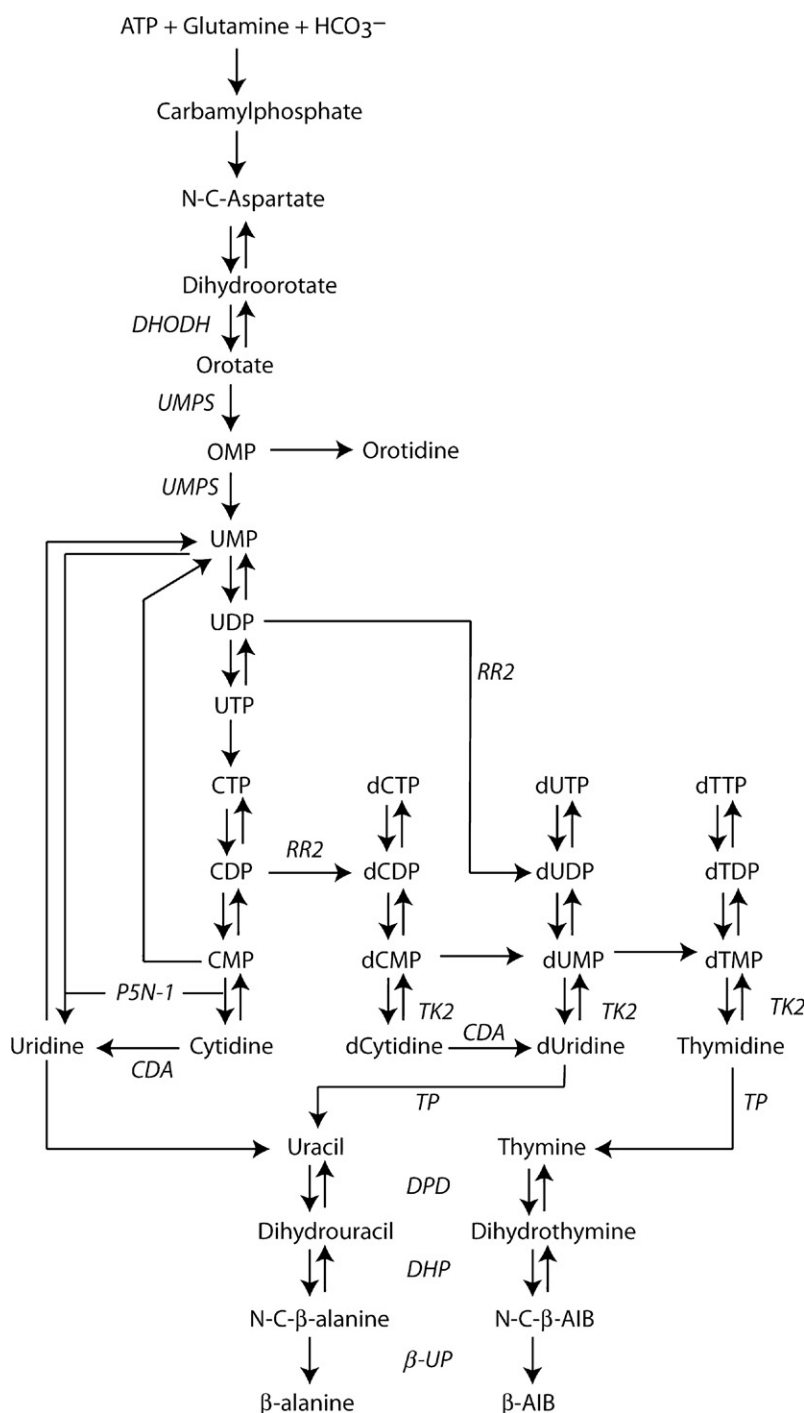

The pyrimidine salvage pathway, composed of kinases, converts the pyrimidine nucleosides, (deoxy)cytidine, (deoxy)uridine, and thymidine, into the corresponding nucleotides, (deoxy)CMP, (deoxy)UMP, and TMP.

#### 95.3.2 Hereditary Orotic Aciduria (UMP Synthetase Deficiency)

Hereditary orotic aciduria was the first inborn error discovered in pyrimidine metabolism (16). It is caused by a deficiency of the last two steps of *de novo* pyrimidine synthesis, orotate phosphoribosyltransferase (OPRT), and orotidine 5'-monophosphate decarboxylase (ODC). Both steps are catalyzed by a single, bifunctional polypeptide termed uridine monophosphate (UMP) synthase (see Figure 95-4). Hereditary orotic aciduria (MIM 258900) is exceedingly rare, with less than 20 cases published over nearly five decades, but early recognition of the disorder is mandatory because it can be easily treated with apparently very good results (227).

**95.3.2.1 Clinical Features.** Patients with hereditary orotic aciduria appear normal at birth but present at a few weeks or months of age with lethargy and failure to thrive, which, untreated, will be followed by developmental delay. Moderate to severe hypochromic anemia is found, with reticulocytes in the normal to low range. Peripheral blood smears show megaloblastosis with severe anisocytosis and poikilocytosis, and moderate hypochromia. Bone marrow examination reveals erythroid hyperplasia and numerous megaloblastic erythroid precursors. In some patients, anemia responded to the treatment with various vitamins, steroids, and hematinics, but characteristically, megaloblastosis persisted. Renal tract obstruction by crystals and infections with various abnormalities of immune function are found in some patients. Unrecognized, the disorder may lead to impairment of growth and cognition.

**95.3.2.2 Diagnostic Tests.** Urinary analysis reveals a massive overexcretion of orotic acid, reaching, in infants, 200- to 1000-fold the normal adult value of 1–1.5 mg per 24 h. This may result in orotic crystalluria, particularly on dehydration. Orotic acid and orotidine can be detected by various techniques including HPLC-UV and HPLC-electrospray tandem mass spectrometry of liquid urine or urine-soaked filter paper

**FIGURE 95-4** Schematic representation of pyrimidine metabolism. Inborn errors of pyrimidine metabolism are depicted in italics. CDA, cytidine deaminase; DPD, dihydropyrimidine dehydrogenase; DHODH, dihydroorotate dehydrogenase; DHP, dihydropyrimidinase; P5N-1, Pyrimidine 5'-nucleotidase type-I; TK2, thymidine kinase 2; TP, thymidine phosphorylase; RR2, ribonucleotide reductase; UMPS, UMP synthase; β-UP, β-ureidopropionase; β-AIB, β-aminoisobutyrate.

strips (228–233). Enzymatic diagnosis can be performed on red blood cells, leukocytes, or fibroblasts. In most patients reported to date, both OPRT and ODC activities were deficient, but remained detectable. This defect is termed type I. To date, no sound data have been published regarding isolated ODC deficiency, referred to as type II. However, pharmacogenetic modeling suggested that patients with orotic

aciduria without megaloblastic anemia are suffering from isolated OPDC deficiency (234).

**95.3.2.3 Biochemical Features.** The two activities of UMP synthase, OPRT and ODC, reside on a single protein containing two domains joined by a linker polypeptide. Limited proteolysis produces separate OPRT and ODC activities, with the former being much more labile than the latter. UMP synthase is composed of two

52-kDa monomers that dimerize and undergo conformational changes to become fully active. The crystal structure of human ODC has been resolved showing plasticity of catalytic residues (235). Studies on patients' cells indicate that UMP synthase deficiency may result from the production of structurally altered proteins that impair the ability of the monomers to form competent, stable dimers.

UMP synthase deficiency provokes, besides massive overproduction of orotic acid, also a deficiency of pyrimidine nucleotides. The overproduction is attributed to the ensuing decrease of the feedback inhibition exerted by the pyrimidine nucleotides, particularly UTP and CTP, on the first enzyme of their *de novo* synthesis, cytosolic carbamoyl phosphate synthetase II (see Figure 95-4). The deficiency of pyrimidine nucleotides leads to impairment of cell division, which results in megaloblastic anemia and in retardation of growth and development.

**95.3.2.4 Molecular Genetics.** UMP synthase is encoded by a single gene, localized on chromosome 3q13, which spans ~15 kb. Three point mutations (R96G, G429R, and V109G) have been identified in two Japanese families (236), among which R96G and V109G are most likely to cause disease. The genetic lesions result in the synthesis of enzymes with reduced stability. Interestingly, deficiency of UMP synthase is estimated to be present in a few percent of Holstein cattle in the United States, in which it seems usually lethal in utero. In the Japanese population, a common polymorphism exists in the OPRT gene with a frequency of 26% (237). This SNP results in an increased activity of OPRT and carriers for this SNP have an increased risk of developing severe grade III–IV diarrhea on treatment with 5-fluorouracil (5FU) (237).

**95.3.2.5 Treatment.** The enzyme defect can be bypassed by the administration of uridine, which is converted into UMP by uridine kinase (see Figure 95-4). An initial dose of 100–150 mg/kg, divided over the day, as a rule induces prompt hematologic response, disappearance of urinary symptoms and infections, and the acceleration of growth. Further dosage has been recommended to be adapted to obtain the lowest possible output of orotic acid. In some cases, normal psychomotor development was achieved, but not in all which may be explained by a delayed onset of therapy.

### 95.3.3 Dihydropyrimidine Dehydrogenase

Dihydropyrimidine dehydrogenase (DPD, EC 1.3.1.2) is the initial and rate-limiting enzyme in the catabolism of pyrimidine bases. It catalyzes the reduction of uracil and thymine to 5,6-dihydrouracil and 5,6-dihydrothymine, respectively (Figure 95-4). Deficiency of DPD (MIM 274270) causes thymine-uraciluria and is typically accompanied by neurological symptoms such as mental and motor delay and convulsions (238,239). However, a consistent phenotype has not yet emerged

(238–240). In addition, DPD plays an important role in the breakdown of the antineoplastic agent 5FU. Patients with a partial or complete enzyme deficiency can suffer from severe and potentially lethal toxicity following 5FU administration (241). Therefore, reliable identification of DPD deficiency is essential to identify cancer patients at risk. Population studies have shown that the prevalence of a partial DPD deficiency in the general population is at least 3–5% (242–244). The carrier frequency in various populations varies considerably (245).

**95.3.3.1 Clinical Features.** The phenotype in patients with DPD deficiency is extremely variable. Many patients are recognized only when they develop a toxic reaction (myelosuppression, diarrhea, fungi infections, and sometimes cardiac toxicity) on 5FU given because of a neoplasm, as they are otherwise completely healthy. Others are detected in metabolic screening because of the search for the cause of developmental delay. Several of these patients have seizures and microcephaly (238,246). Hypotonia and autism or autism spectrum disorders have been described as well (246). Undoubtedly, there is an ascertainment bias and the true clinical phenotype remains to be determined. Patients with DPD deficiency and a marked developmental delay, macrocephaly, and unusual facial morphology may harbor a complete deletion of the gene, and possibly the phenotype is influenced by deletion of neighboring genes as well (247).

The pathological mechanism underlying the various clinical abnormalities is not known. An altered homeostasis of the  $\beta$ -aminoisobutyric acid, a downstream product of thymine, might underlie some of the cerebral dysfunctions often seen in patients with a DPD deficiency (248). The clinical condition of a DPD patient suffering from arthrogryposis multiplex congenita improved considerably when he was treated with both  $\beta$ -alanine and  $\beta$ -AIB (249).

**95.3.3.2 Diagnostics Tests.** DPD deficiency is an autosomal recessive disease characterized by markedly elevated uracil and thymine levels in body fluids such as urine, plasma, and cerebrospinal fluid (231). The concentrations of uracil and thymine in urine range from 47 to 1008 mmol/mol creatinine (controls: 0–30 mmol/mol creatinine) and 7 to 679 mmol/mol creatinine (controls: 0–2 mmol/mol creatinine), respectively. In some cases, 5-hydroxymethyluracil, a metabolite of thymine, is also present in urine and plasma. The pyrimidine catabolites can be detected by various techniques including HPLC, GC–MS analyses of urinary trimethylsilylated organic acid extracts, and HPLC-electrospray tandem mass spectrometry of liquid urine or urine-soaked filter paper strips (228–231,250). The enzyme defect can be demonstrated in the patients' peripheral blood mononuclear cells fibroblasts or liver (251,252).

**95.3.3.3 Biochemical Features.** The activity of DPD is exclusively present in the cytosol and the enzyme is ubiquitously expressed with the highest activity being found in the liver and peripheral blood mononuclear

cells (251). Mammalian DPD appears to be relatively conserved throughout evolution and the high-sequence identities (>92%) between human DPD and that of other mammals, such as bovine and pig, suggest that very similar reaction mechanisms and three-dimensional structures exist in these species (253). The crystal structure of pig DPD revealed that the native enzyme is a homodimer of  $2 \times 111$  kDa and each subunit of 1025 amino acids carries one FAD, one FMN, and four [4Fe-4S] clusters (253). Each subunit appears to be arranged in a highly modular way with five distinctive domains, each carrying a subset of the prosthetic groups. Analysis of the crystal structure of pig DPD suggested that a number of mutations interfered directly or indirectly with cofactor binding or electron transport or affected the structural integrity of the DPD protein (239).

**95.3.3.4 Molecular Genetics.** DPD deficiency is an autosomal recessive disorder and *DPYD* is present as a single copy gene on chromosome 1p21.3 and consists of 23 exons (254). Physically, *DPYD* is at least 950 kb in length with 3 kb of coding sequence and an average intron size of 43 kb (254). The common fragile site *FRA1E* extends over 370 kb within *DPYD* and the region with the highest fragility encompasses exons 13–16 of *DPYD* (255). To date, more than 50 mutations and polymorphisms in the DPD gene have been reported. Analysis of the prevalence of the various mutations among DPD patients has shown that the c.1905+1G>A (IVS14+1G>A) mutation is by far the most common (238,241). This mutation leads to skipping of exon 14, immediately upstream of the mutated splice donor site, in the process of DPD pre-mRNA splicing. A high prevalence of the c.1905+1G>A mutation in the Dutch population was observed, with 1.8% heterozygotes (256). Recently, a deep intronic mutation affecting pre-mRNA splicing in the dihydropyrimidine dehydrogenase gene has been identified (257). Furthermore, the presence of genomic deletions affecting *DPYD* has been demonstrated in 7% (5/72) of all DPD-deficient patients (246). To date, no clear genotype–phenotype correlation has been established, but it is noteworthy that patients with gross deletions in *DPYD* presented with a severe phenotype when compared to that observed in other DPD patients (238,239).

### 95.3.4 Dihydropyrimidinase Deficiency

Dihydropyrimidinase (DHP) is the second enzyme of the pyrimidine degradation pathway and catalyzes the ring opening of 5,6-dihydrouracil and 5,6-dihydrothymine. To date, only 28 patients have been described with a complete DHP deficiency (MIM 222748), including five symptomless individuals who were identified by a screening program for inborn errors of pyrimidine degradation (258). The enzymes of the pyrimidine degradation pathway are also involved in the degradation of the antineoplastic agent 5FU (241). Patients with a DHP

deficiency have developed severe 5FU-associated toxicity (259–261).

**95.3.4.1 Clinical Features.** Clinical features in 20 DHP deficient patients showed a considerable variation in presentation (258). Mental retardation, hypotonia, and seizures were observed in 63%, 45%, and 30% of the patients, respectively. Growth retardation, failure to thrive, microcephaly, and autism were observed less frequently. Forty-five percent of the patients presented with gastrointestinal problems (feeding problems, cyclic vomiting, gastroesophageal reflux, malabsorption with villous atrophy). One patient suffered from a combined deficiency of DHP and a tyrosinemia type II and another patient had both DHP deficiency and congenital microvillous atrophy (262). Phenotypic variability of DHP deficiency was demonstrated in two families in which the index patient was clinically affected whereas the same genotype did not lead to overt symptoms in siblings. It is likely the phenotype is markedly influenced by (epi) genetic and/or environmental factors.

**95.3.4.2 Diagnostic Tests.** DHP deficiency is characterized by markedly elevated dihydrouracil and dihydrothymine levels in body fluids such as urine, plasma, and cerebrospinal fluid (258). The concentrations of dihydrouracil and dihydrothymine in urine range from 100 to 849 mmol/mol creatinine (controls: 0–31 mmol/mol creatinine) and 46 to 622 mmol/mol creatinine (controls: 0–10 mmol/mol creatinine), respectively. The dihydropyrimidines can be detected by various techniques including GC–MS analyses of urinary trimethylsilylated organic acid extracts and HPLC-electrospray tandem mass spectrometry of liquid urine or urine-soaked filter paper strips (229,231,250). Enzyme assay requires liver biopsy, because more accessible tissues do not possess significant DHP activity (263,264).

**95.3.4.3 Biochemical Features.** DHP has been purified and characterized in eukaryotic species and the DHP crystal structures from the yeast *Saccharomyces kluyveri* (<sup>Sk</sup>DHP), the slime mold *Dictyostelium discoideum* (<sup>Dd</sup>DHP), and human DHP have recently been determined (265–269). These studies showed that the native enzyme is composed of four identical subunits containing two zinc ions. In addition, a high structural resemblance between eukaryotic DHP proteins and those of hydantoinases, the bacterial counterparts of DHP as well as the DHP-like noncatalytic proteins involved in neuronal development was observed.

**95.3.4.4 Molecular Genetics.** The gene encoding DHP, *DPYS*, maps to chromosome 8q22 and consists of 10 exons spanning >80 kb of genomic DNA (270). The cDNA coding for human DHP contains an open reading frame of 1560 nucleotides, corresponding to a protein of 519 amino acids with a calculated molecular weight of 56,629 Da (270). *DPYS* analysis has been published in 24 patients showing 21 mutations, including 14 missense mutations, 2 nonsense mutations, 2 deletions, 1 insertion, and 1 splice-site mutation (258,270). Crystal

structures have been shown to be useful in explaining functional compromises of the enzyme (258). Heterologous expression of the mutant enzymes in *Escherichia coli* resulted in mutant enzymes without significant residual activity (258,270).

### 95.3.5 $\beta$ -Ureidopropionase Deficiency

$\beta$ -Ureidopropionase (EC 3.5.1.6). (also termed  $\beta$ -alanine synthase) catalyzes the last step of the pyrimidine degradation pathway, the conversion of *N*-carbamyl- $\beta$ -alanine and *N*-carbamyl- $\beta$ -aminoisobutyric acid into  $\beta$ -alanine and  $\beta$ -aminoisobutyrate, respectively.

To date, only five patients suffering from a complete  $\beta$ -ureidopropionase deficiency have been reported (19,271). However, during a neonatal screening in Japan, five additional asymptomatic children with a putative  $\beta$ -ureidopropionase deficiency were identified (272,273). Acquired (secondary)  $\beta$ -ureidopropionase deficiency has been reported with severe forms of propionic acidemia, due to the inhibition of this enzyme by propionic acid (274).

**95.3.5.1 Clinical Features.** The clinical phenotype of  $\beta$ -ureidopropionase deficiency is characterized by a severe cognitive defect, hypotonia, and delayed motor development and scoliosis, seizures starting in the first months of life, and sometimes dystonia and autism. However, patients that develop normal cognitively have also been found. A single patient had a bladder extrophy with several additional malformations (271).

To date, the mechanism underlying the clinical symptoms observed in our patients with a  $\beta$ -ureidopropionase deficiency is not known. It has been suggested that *N*-carbamyl- $\beta$ -alanine, one of the accumulating substrates, might function as an endogenous neurotoxin (275) as high concentrations of *N*-carbamyl- $\beta$ -alanine inhibited the mitochondrial energy metabolism, which was accompanied by the induction of oxidative stress. The observation, however, that the concentrations of *N*-carbamyl- $\beta$ -alanine were only marginally elevated in CSF of the patients argues against a direct role of *N*-carbamyl- $\beta$ -alanine in the neuropathology. Treatment of a patient with  $\beta$ -alanine for 1.5 years did not result in clinical improvement (276).

**95.3.5.2 Diagnostic Tests.**  $\beta$ -Ureidopropionase deficiency is characterized by markedly elevated *N*-carbamyl- $\beta$ -alanine and *N*-carbamyl- $\beta$ -aminoisobutyric acid levels in body fluids such as urine, plasma, and cerebrospinal fluid (271,273). The concentrations of *N*-carbamyl- $\beta$ -alanine and *N*-carbamyl- $\beta$ -aminoisobutyric acid in urine range from 691 to 745 mmol/mol creatinine (controls: 1–53 mmol/mol creatinine) and 490 to 687 mmol/mol creatinine (controls: 0–11 mmol/mol creatinine), respectively. The *N*-carbamyl- $\beta$ -amino acids can be detected by various techniques including GC–MS analyses and HPLC-electrospray tandem mass spectrometry of liquid urine or urine-soaked filter paper strips (229,250,273).

Enzyme assay requires liver biopsy, because more accessible tissues do not possess significant  $\beta$ -ureidopropionase activity (263,277).

**95.3.5.3 Biochemical Features.** Mammalian  $\beta$ -ureidopropionase appears to have been only relatively conserved throughout evolution, as a comparison of the deduced amino acid sequences of human  $\beta$ -ureidopropionase with that of rat, showed a homology of 84%. Nevertheless, the analysis of a variety of eukaryotic  $\beta$ -ureidopropionases showed that they are functionally related, despite a high degree of structural diversity (278). The native human enzyme is most likely composed of eight identical subunits (279).

**95.3.5.4 Molecular Genetics.** The *UPB1* gene has been mapped to chromosome 22q11.2 and consists of 11 exons spanning ~20 kb of genomic DNA. The cDNA coding for human  $\beta$ -ureidopropionase contains an open reading frame of 1152 nucleotides, corresponding to a protein of 384 amino acids with a calculated molecular weight of 43,158 Da (280). Analysis of *UPB1* in 5 patients showed 2 missense mutations and 2 splice-site mutations (19,271). It may be that missense mutations are more likely to go along with limited neurological problems but numbers are too small to allow for firm conclusions. Heterologous expression of the mutant enzymes in *E. coli* resulted in mutant enzymes without significant residual activity (19,271).

### 95.3.6 Pyrimidine 5'-Nucleotidase Deficiency

Purine and pyrimidine nucleotides are converted to their corresponding nucleosides by a variety of cytosolic and membrane 5'-nucleotidases that may be more specific for one or another type of nucleotide. Several pyrimidine 5'-nucleotidases (P5N) exist that dephosphorylate CMP, UMP, their deoxy counterparts, and TMP to the corresponding nucleosides (Figure 95-4). The deficiency of one of these, pyrimidine 5'-nucleotidase type-I (P5N-1), and isozyme restricted to erythrocytes that catalyze the dephosphorylation of UMP and CMP but not of TMP, was identified in patients with severe chronic hemolytic anemia (MIM 266120). P5N-1 is also involved in the dephosphorylation of nucleoside monophosphates of analogs, such as gemcitabine and AraC (281). To date, ~99 patients have been reported (282,283).

**95.3.6.1 Clinical Features.** Hereditary P5N-1 deficiency is thought to be one of the most common causes of chronic nonspherocytic hemolytic anemia. Patients present with anemia and all consequences of long-term anemia such as hepatosplenomegaly, jaundice, and gallstones. Infrequently, patients show a cognitive delay as well, but it remains uncertain whether this is related. Characteristically, the anemia is nonspherocytic, reticulocytosis may be as high as 45%, and there is prominent basophilic stippling. The basophilic stippling is caused

by the accumulation of high concentrations of pyrimidine nucleotides, mainly CTP and UTP, in the erythrocytes. The mechanism by which the increased pyrimidine nucleotides cause hemolysis remains elusive, but the interference of the accumulating pyrimidine nucleotides with glycolysis, pentose phosphate shunt activity, and altered membrane phospholipid composition has been suggested (282).

**95.3.6.2 Diagnostic Tests.** The diagnosis depends on the demonstration of high concentrations of pyrimidine nucleotides and a reduced P5N-1 activity in red blood cells. Normal red cells contain predominantly purine nucleotides (which have an absorption maximum at ~260 nm) with very low levels of pyrimidine nucleotides (absorption at 280 nm). In P5N-1 deficiency, high levels of pyrimidine nucleotides accumulate in erythrocytes, resulting in a decreased 260:280 absorbance ratio. The analysis of the P5N-1 activity can be performed using a variety of procedures including HPLC-UV. Residual P5N-1 activity has been reported to vary from 1 to 64% and is not correlated with the degree of hemolysis.

**95.3.6.3 Biochemical Features.** Pyrimidine 5'-nucleotidase type-I (P5N-1) is also called cytosolic 5'-nucleotidase III (cNIII) or uridine monophosphate hydrolase type I (UMPH-1) and is a 34 kDa monomeric protein preferentially catalyzing the dephosphorylation of UMP and CMP to their corresponding nucleosides and it is inactive toward purine nucleotides. The activity is dependent on the presence of magnesium ions and it is readily inhibited by heavy metals. Consequently, subjects with chronic low-level lead poisoning may develop severe acquired deficiency of P5N-1, which also results in anemia and basophilic stippling. Clearing of lead returns the nucleotidase activity to normal and resolves the anemia. P5N-1 also displays phosphotransferase activity specific for pyrimidine nucleosides, suggesting an additional role in nucleotide metabolism.

**95.3.6.4 Molecular Genetics.** The gene encoding P5N-1 (*NT5C3*) is localized on 7p15-p14 and consists of 11 exons leading to three alternatively spliced mRNAs (283,284). Since the identification of the P5N-1 gene in 2001, ~24 mutations have been reported in about 40 patients (285). Approximately two-thirds of the mutations are deletions–insertions, generation of nonsense codons, or alternation of splice sites that are most likely causing complete absence of the protein or a truncated version of the protein. Functional analysis of some of the missense mutations showed that the corresponding mutant proteins possessed impaired catalytic activity and/or a reduced thermostability (285,286). Analysis of *NT5C3* in 240 ethnically defined DNA samples revealed 60 polymorphisms and the genetic variation in *NT5C3* has been associated with altered protein function and a potential difference in response to araC and gemcitabine (281).

### 95.3.7 Cytosolic 5'-Nucleotidase Superactivity

An increased activity (6–10-fold) of the cytosolic 5' nucleotidase has been identified in nine patients (21,287) showing a cognitive delay, hyperactivity, and seizures. Routine laboratory tests were unremarkable except for persistent hypouricosuria, explained tentatively by a 30–50% lower concentration of PRPP, as found in patients' fibroblasts, caused by the salvage of the purine bases derived from increased nucleotide catabolism. Decreased PRPP would result in decreased de novo purine synthesis and hence decreased uric acid production. Based on the possibility that increased catabolism might cause a deficiency of pyrimidine nucleotides, patients were treated successfully with oral uridine. Since the initial reports no subsequent patients have been reported and the exact meaning of the findings remains uncertain. A putative nucleotidase responsible for the AMP hydrolyzing hyperactivity has recently been identified (288).

### 95.3.8 Thymidine Phosphorylase Deficiency

Thymidine phosphorylase (TP), also known as “platelet-derived endothelial cell growth factor” (PD-ECGF) and glyostatin, catalyzes the first step in the degradation of the pyrimidine deoxynucleosides thymidine and deoxyuridine (Figure 95-4). Besides natural 2'-deoxynucleosides, TP also recognizes several pyrimidines or pyrimidine nucleosides with antiviral and antitumoral activity, such as 5-fluoro-5'-deoxyuridine (5'DFUR), an intermediate metabolite of capecitabine. TP is found in many normal tissues and cells. Blood platelets are one of the richest sources of TP, which suggests a role for the enzyme in wound healing. Furthermore, TP plays an important role in the female reproductive cycle. TP is upregulated in a wide variety of solid tumors including breast and colorectal cancers. TP promotes tumor growth and metastasis by preventing apoptosis and inducing angiogenesis. Elevated levels of TP are associated with tumor aggressiveness and poor prognosis (22,289). TP is also involved in a wide variety of chronic inflammatory diseases and a deficiency causes mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) (MIM 603041) (35,290).

**95.3.8.1 Clinical Features.** MNGIE is characterized by ptosis, progressive external ophthalmoplegia, severe gastrointestinal dysmotility, cachexia, peripheral neuropathy, hearing loss, and skeletal myopathy (290). The initial symptoms are often weight loss and diarrhea, often in the second or third decade (mean 19 years), but much earlier or later has also been reported. Vomiting and periods of pseudo-obstruction occur. The neurological problems are usually relatively mild. The MRI may show a leukoencephalopathy, but this remains usually asymptomatic. The gastrointestinal problems are progressive, and most patients die in the fourth decade.

In patients with MNGIE, the markedly elevated levels of thymidine and deoxyuridine in plasma may cause unbalanced mitochondrial nucleoside and nucleotide pools, which lead to impaired mitochondrial DNA replication and repair. Therefore, therapies that decrease thymidine and deoxyuridine levels may be beneficial to MNGIE patients such as infusion of platelets, dialysis, and allogeneic stem cell transplantation (291–294).

**95.3.8.2 Diagnostic Tests.** In patients with MNGIE, no or a severely reduced TP activity was detected in leukocytes that was accompanied by the presence of strongly elevated levels of thymidine and deoxyuridine in plasma (295–297). In contrast, carriers for mutations in the TP gene, resulting in a substantially reduced activity of TP, did not show the elevated levels of thymidine and deoxyuridine (297). A diagnostic algorithm has been developed based on the analysis of thymidine and deoxyuridine in plasma and the determination of the TP activity in leukocytes, to ensure the proper diagnosis of patients suffering from MNGIE (297). The TP activity can be measured in leukocytes using a non-radiolabel assay, which is based on the separation of thymine and thymidine using reversed-phase HPLC (298). An analysis of thymidine and deoxyuridine concentrations in plasma can be performed using HPLC-UV (297) or HPLC-tandem mass spectrometry (228–230).

**95.3.8.3 Biochemical Features.** TP is a dimer consisting of two identical subunits with a molecular weight of 50 kDa for the monomer. Intracellularly, TP is present in the cytosol and the nucleus. TP catalyzes the conversion of thymidine and 2'-deoxyuridine to their respective bases and 2- $\alpha$ -D-deoxyribose-1-phosphate. Although this reaction is reversible, the most important metabolic function of TP is catabolic. TP also has deoxyribosyl transferase activity by which the deoxyribosyl moiety is transferred from a pyrimidine nucleoside to another pyrimidine base, resulting in the formation of a new pyrimidine nucleoside. Besides natural 2' deoxynucleosides, TP also recognizes several pyrimidines or pyrimidine nucleosides with antiviral and antitumoral activities, such as 5-(E)-(2-bromovinyl)-20-deoxyuridine, 5-trifluorothymidine, 5-fluorouracil, and 5-fluoro-5'-deoxyuridine (289). Specific amino acids in human TP, required for enzymatic activity, have been identified through analysis of the crystal structure and the characterization of mutant proteins (300). There is no correlation between the enzymatic activity of TP and the clinical severity on MNGIE.

**95.3.8.4 Molecular Genetics.** The TP gene (*TYMP*) is located on chromosome 22q13.33 and is composed of 10 exons. Homozygosity for loss-of-function mutations of the TP gene have been identified as the possible cause for MNGIE (35,290,293) making it an autosomal recessively inherited disorder. To date, more than 50 mutations have been identified in *TYMP* in more than 40 families with one or more MNGIE patients (293). No clear genotype–phenotype correlation has emerged.

### 95.3.9 Dihydroorotate Dehydrogenase Deficiency

Dihydroorotate dehydrogenase (DHODH) is the fourth enzyme of the pyrimidine de novo pathway and it catalyzes the conversion of dihydroorotate to orotate. In most eukaryotes, DHODH is localized in mitochondria and the electrons are transferred directly to the respiratory chain via ubiquinone. Inhibitors of DHODH, such as brequinar sodium and leflunomide, have been successfully tested as antiproliferative agents that interfere with neoplastic growth and suppress immunological reactions. DHODH inhibitors have been considered as potential agents for a wide range of parasitic infections (301,302). There have been eight patients published with a DHODH deficiency who showed clinically Miller syndrome (MIM 263750) (23,303).

**95.3.9.1 Clinical Features.** Miller syndrome is characterized by an underdevelopment of the malar bones causing prominence of the eyes, downsloping of the palpebral fissures, and ectropion of the lower eyelids, a small jaw, frequently cleft lip with a cleft palate, and distal limb anomalies (acro-facial dysostosis). The limb anomalies consist of absence or incomplete development of the fifth ray of both hands and feet, and sometimes underdevelopment of the lower arms and lower legs, or underdevelopment of the thumbs is also found. Infrequently, deafness and heart defects are found and sometimes there is a cognitive defect, but most patients develop normally.

**95.3.9.2 Diagnostic Tests.** To date it is not known yet whether patients with a DHODH deficiency present with elevated levels of dihydroorotate or *N*-carbamylaspartate. A dedicated method has been developed for analyses of pyrimidine de novo metabolites using HPLC-electrospray tandem mass spectrometry of liquid urine or urine-soaked filter paper strips (232). The diagnosis is performed using sequence analysis of the DHODH gene.

**95.3.9.3 Biochemical Features.** Mammalian DHODH is a 43 kDa flavoprotein (FMN) localized at the inner mitochondrial membrane, facing the intermembrane space (304). For its activity, mitochondrial DHODH depends on a functional respiratory chain and requires ubiquinone as a direct electron acceptor (305). Mitochondrial import is governed by an uncleaved bipartite sequence at the N-terminus of the protein that consists of a mitochondrial targeting sequence and a membrane stop-transfer sequence that anchors the protein to the inner membrane (304). Structural studies have shown that the truncated enzyme, lacking the bipartite sequence, is fully active (305,306). Detailed analysis of the crystal structure of DHODH has been proven useful for the development of new inhibitors (307).

**95.3.9.4 Molecular Genetics.** The human DHODH gene is located on chromosome 16q22.2 and contains nine exons (23). Collectively, 11 different mutations

have been identified in 6 patients with Miller syndrome by a combination of total exom sequencing and targeted resequencing (23). Ten of these mutations were missense mutations and one was a 1-bp indel that is predicted to cause a frameshift and a termination codon 7 amino acids downstream. Each of the amino acid residues affected by a DHODH mutation was highly conserved among homologs studied to date (23). A polymorphism in the DHODH gene (c.19C>A) has been shown to be associated with toxicity and treatment outcome with leflunomide of patients suffering from rheumatoid arthritis (308,309).

### 95.3.10 Cytidine Deaminase Deficiency

Cytidine deaminase (CDA; MIM 123920) is one of the enzymes of the pyrimidine salvage pathway and it catalyzes the deamination of (deoxy)cytidine into (deoxy)uridine. CDA is able to deaminate, and in this way inactivate, the antitumor agents ara-C and gemcitabine. The pivotal role of CDA in the metabolism of ara-C and gemcitabine is highlighted by the identification of CDA-deficient patients suffering from severe toxicity on treatment with ara-C or gemcitabine (24,310). Although patients with a complete CDA deficiency are rare, it has been suggested that 7% of adult patients with cancer have a partial CDA deficiency and thus an increased risk to develop severe gemcitabine-associated toxicity (310). CDA is also an indispensable enzyme in the metabolism of capecitabine and a high CDA activity has been associated with severe 5FU toxicity (311).

**95.3.10.1 Clinical Features.** Individuals with a CDA deficiency have no known phenotype unless treated with gemcitabine because of cancer such as esophagus carcinoma, lung cancer, pancreas cancer, and also acute lymphoblastic leukemia in children, which may cause marked toxic reactions (312).

**95.3.10.2 Diagnostic Tests.** CDA deficiency (or increased activity) can be established by analysis of the CDA activity in plasma (310,311). In patients suffering from severe toxicities after gemcitabine administration, the mean CDA activity in plasma was ~25% of that observed in patients with no toxicity (310). Analysis of the CDA gene can be performed for the presence of the c.208G>A mutation, for which a clear association with gemcitabine toxicity, has been observed in Japanese patients (313,314).

**95.3.10.3 Biochemical Features.** Human CDA is a homotetramer with a molecular weight of the monomer of 14.9kDa. Each of the four subunits links a zinc atom, which is essential for the enzymatic activity. No cooperativity exists between the subunits and the monomer is inactive. Critical residues involved in the intersubunit interaction have been identified via analysis of the mutant proteins (315). CDA purified from human placenta revealed the presence of five

isoenzymatic forms that differ only in their isoelectric point, which has been ascribed to the existence of two variants with a nonconservative amino acid substitution at codon 27 (316). CDA is readily expressed in human tissues (317).

**95.3.10.4 Molecular Genetics.** The CDA gene is located at chromosome 1p36.12 and the gene is composed of four exons. To date, more than 30 genetic variations have been identified in the CDA gene (312,313,318). The c.208G>A mutation (p.A70T) has been shown to be associated with reduced CDA activity, altered gemcitabine pharmacokinetics, and severe gemcitabine-associated toxicity (24,313,314). Analysis of the prevalence of this mutation in various populations showed that the mutation could only be detected in Japanese and Korean subjects and not in African-, Caucasian- and Chinese-Americans (319). Conflicting data exist as to whether the c.79A>C polymorphism is associated with altered gemcitabine pharmacokinetics (320).

### 95.3.11 Thymidine Kinase 2 Deficiency

Human mitochondrial thymidine kinase 2 (TK2) is a pyrimidine deoxynucleoside kinase, which catalyzes the phosphorylation of pyrimidine deoxynucleosides to their corresponding deoxynucleoside 5'-monophosphates. In resting cells, TK2 plays a key role in the mitochondrial salvage pathway to provide pyrimidine nucleotides for mitochondrial DNA (mtDNA) synthesis and maintenance (321,322). TK2 is also able to phosphorylate a number of chemotherapeutic drugs and antiviral agents (323). This phenomenon might underlie the mitochondrial toxicity associated with prolonged treatment with antiviral nucleoside analogs, such as AZT and FIAU. A deficiency of TK2 is a frequent cause of isolated myopathy or encephalomyopathy in children with mtDNA depletion (mtDNA depletion syndrome type 2; MIM 609560) (25).

**95.3.11.1 Clinical Features.** The mitochondrial depletion syndrome caused by TK2 mutations is usually characterized by neonatal hypotonia and lactic acidosis, and subsequent encephalopathy, liver failure, or renal tubulopathy. In most patients, the disorder is fatal before 6 years of age due to respiratory failure (323). However, the variability can be marked and longer survival, even into the third decade, has been described, and symptoms may be restricted to a pure myopathy.

**95.3.11.2 Pathological Mechanism.** During cell growth, cytosolic dNTPs are synthesized via the S-phase specific de novo synthesis catalyzed by the canonical R1/R2 form of ribonucleotide reductase and the salvage via thymidine kinase 1 (TK1). In postmitotic cells, in which the cytosolic dNTP synthesis is downregulated, mtDNA synthesis relies heavily on the mitochondrial salvage pathway enzymes TK2 and dGK. Therefore, individuals with defects in TK2 show decreased intramitochondrial

TTP pools resulting in imbalance of the TTP/dCTP ratio (324,325). It has been suggested that such mitochondrial nucleotide imbalances could affect the accuracy or the rate of mtDNA synthesis (25,326). The low basal TK2 activity with a high requirement for mitochondrial encoded proteins has been proposed as the main determinant of the muscle involvement in TK-2 deficient individuals (326). In addition, it has been suggested that the onset and organ specificity of TK2 deficiency is dependent on TK1 down-regulation and transcriptional compensation mechanisms to the reduced mtDNA levels (327).

**95.3.11.3 Diagnostic Tests.** The enzyme defect can be demonstrated by analysis of the TK2 activity in mitochondria isolated from muscle or fibroblasts (25,326,328). It has been reported that the activity of TK2 in muscle mitochondria is reduced to 14–45% of the mean value in healthy control individuals (25). Analysis of the TK2 activity in whole cell lysates, containing two interfering deoxyribonucleoside kinases thymidine kinase 1 and deoxycytidine kinase, can be performed using bromovinyl-deoxyuridine, a selective TK2 substrate (329,330).

**95.3.11.4 Biochemical Features.** Human TK2 catalyzes the conversion of thymidine, deoxyuridine, and deoxycytidine into TMP, dUMP, and dCMP, respectively (322). In addition, various nucleoside analogs used as antivirals, can be converted to the corresponding nucleoside monophosphates (322). Although TK2 is predominantly localized into mitochondria, a cytosolic form has been identified as well (331). TK2 is expressed in all tissues in proportion to the mitochondrial content of the cell type. Mature human TK2 consists of 232 amino acids with a subunit molecular weight of 27,487Da (332,333). Human TK2 is active both as a dimer and a tetramer (332,334).

**95.3.11.5 Molecular Genetics.** At present, at least 16 point mutations, deletions and insertions have been reported in TK2 of 20 patients with TK2 deficiency (335). Ten patients proved to be compound heterozygotes and mutations were fairly evenly distributed from exon 3 to exon 10 (335). The effect of several point mutations has been investigated in detail by the expression of mutant proteins followed by the characterization of enzyme function (328,333,335,336). Overall, there was a tendency of a slower progression of manifestations if the mutant TK2 proteins showed some enzyme activity (328,336).

## ACKNOWLEDGMENTS

We would like to acknowledge the authors of the previous editions, J E Seegmiller, M-F Vincent, and G van den Berghe, that were used as the basis of this chapter.

### Biographies

**Naoyuki Kamatani** is the director of Center for Genomic Medicine (CGM), RIKEN Yokohama Institute Yokohama, Japan. He is a statistical geneticist as well as a rheumatologist. Prior to his current position, he had been the director of and professor at the Institute of Rheumatology, Tokyo Women's Medical University, where he served as a clinical rheumatologist. His publications cover a quite wide area of medicine spanning from cancer genetics, nucleic acid metabolism, gout, rheumatic diseases, monogenic diseases, statistical genetics, and pharmacogenomics. Recently, he especially focuses on genome-wide association studies (GWASs) targeted at a variety of human traits including diseases, drug reactions, and laboratory test values like urate. He is one of the pioneers who developed the technologies of GWAS from the aspect of statistical genetics.

**H A Jinnah** received his MD and PhD degrees from the University of California in San Diego, California. He completed residency training in Neurology at Johns Hopkins University in Baltimore Maryland. Currently, he is Professor of Neurology, Human Genetics and Pediatrics at Emory University in Atlanta, Georgia. He sees patients in the clinic and hospital one day per week, and spends the rest of his time in research. His research interests include both basic and clinical research on Lesch–Nyhan disease and other forms of dystonia. He is the founding director of the International Lesch–Nyhan Disease Study group and the director of the Dystonia Coalition, a multicenter network for clinical and translational research. He has published more than 100 articles. His funding comes from the NIH and several private foundations.

**Raoul C M Hennekam** received his MD degree and his specialty trainings in Pediatrics and a second one in Clinical Genetics at the State University of Utrecht, The Netherlands. He was appointed as professor of Pediatrics and Clinical Genetics in 2002 at the Academic Medical Centre of the University of Amsterdam. Between 2005 and 2010, he worked in London at the Institute of Child Health and Great Ormond Street Hospital for Children at the University College London as a professor of Clinical Genetics and Dysmorphology. He is presently working as a professor of Pediatrics and Translational Genetics in Amsterdam again, and as honorary professor of Clinical Genetics at the Institute of Neurology at University College, London. His main scientific interests include mental disabilities, autism, connective tissue disorders, and (molecular) dysmorphology. He is the European Editor of the *American Journal of Medical Genetics*, editor of the *European Journal of Medical Genetics*, member of the editorial board of eight other medical journals, author of 400 papers in the international literature and of 12 chapters in international texts, chair of the international nomenclature committee, and senior editor of the major text in Dysmorphology “Gorlin’s Syndromes of the Head and Neck”.

**André B P van Kuilenburg** received his MSc degree (Honors) in Chemistry (First Class in Biochemistry) in 1986 and his PhD in 1992 from the University of Amsterdam, The Netherlands. In 2003, he was registered as a specialist in clinical genetic laboratory diagnostics with emphasis on clinical biochemical genetics. He is presently working as a clinical biochemical geneticist and principal investigator at the Academic Medical Centre of the University of Amsterdam. His main scientific interests are inborn errors of purine and pyrimidine metabolism, pharmacogenetic aspects associated with inborn errors of the pyrimidine degradation pathway, and biochemical aspects of pediatric oncological diseases. He is the author of 215 scientific papers in peer-reviewed international journals and books. He is a member of the scientific committee of the Purine and Pyrimidine Society and has been elected the secretary of the Dutch Society for Inborn Errors of Metabolism.

## Lipoprotein and Lipid Metabolism

*Robert A Hegele*

Robarts Research Institute and Schulich School of Medicine and Dentistry,  
University of Western Ontario, London, Ontario, Canada

This article is a revision of the previous edition article by Aldons J. Lusis, Peter S Gargalovic, Lawrence W Castellani and Jesus A Araujo, volume 2, pp 2247–2283, © 2007, Elsevier Ltd.

### ABBREVIATIONS

AD – autosomal dominant  
AR – autosomal recessive  
BA – bile acid  
CHD – coronary heart disease  
CM – chylomicron  
CVD – cardiovascular disease  
HDL – low-density lipoprotein  
HLP – hyperlipoproteinemia  
HTG – hypertriglyceridemia  
IDL – intermediate-density lipoprotein  
LDL – low-density lipoprotein  
LRP – LDL receptor related protein  
MIM – Mendelian Inheritance in Man  
TG – triglyceride  
PL – phospholipid  
VLDL – very-low-density lipoprotein

Alpha, beta, pre-beta and broad-beta lipoproteins: It is possible to classify lipoproteins as “alpha” and “beta” based on their mobility through serum protein electrophoretic gels, according to their position. HDL subfractions have alpha mobility, LDL subfractions have beta mobility, VLDL fractions have pre-beta mobility and the spectrum of remnant triglyceride-rich lipoprotein particles, including IDL, have broad-beta mobility. These electrophoretic phenotypes give rise to names of clinical syndromes of disordered lipoprotein metabolism, such as “abetalipoproteinemia,” “hypo-beta lipoproteinemia” and “hypoalphalipoproteinemia.”

### 96.1 INTRODUCTION

Lipoproteins transport hydrophobic lipids and fat-soluble vitamins through plasma from their site of origin (intestine or liver) to their site of uptake and disposition. Abnormal

levels of certain plasma lipids and lipoproteins increase the risk of cardiovascular disease (CVD) end points, such as myocardial infarction and stroke (1). A wide range of genetic and environmental factors contribute to inter-individual variation in plasma concentrations of lipids and lipoproteins (2). Dyslipidemias that have a monogenic basis typically present earlier in life, while those that present later in life also have genetic determinants but their expression further depends on interactions with nongenetic environmental or lifestyle factors (3). Early diagnosis is central to specific dietary, lifestyle and pharmacological interventions to delay death, disability and medical complications (4). This chapter will review the current understanding of genetic determinants, clinical manifestations and treatment modalities associated with disorders of lipoprotein and lipid metabolism, including disturbances affecting levels of cholesterol (hyper- and hypocholesterolemia), triglycerides (TGs) (hypertriglyceridemia (HTG)) and some related conditions.

### 96.2 PLASMA LIPIDS, LIPOPROTEINS AND APOLIPOPROTEINS

The most important plasma lipids clinically are cholesterol and triglyceride (also called triacylglycerol) (2). Cholesterol is (1) a component of cell membranes; (2) the precursor for steroid hormones and vitamin D, and for oxysterols and bile acids (BAs), both activators of nuclear hormone receptors involved in sterol metabolism; and (3) required for the activation of neuronal signaling molecules (5). Relatively little circulating cholesterol originates from the diet; ~80% is derived from endogenous synthesis in the liver and extrahepatic tissues. Fat or carbohydrate not required by the liver for

FIGURE 96-1 Lipoprotein metabolism.

TABLE 96-1 Main Lipoprotein Classes

Lipo-protein Class	Size Range (nm)	Density Range (g/mL)	Electrophoretic Mobility	TG (%wt)	PL (%wt)	Free Cholesterol (%wt)	Esterified Cholesterol (%wt)	Protein (%wt)	Main Apolipoproteins
CMs	75–120	0.94	Origin (cathode)	80–95	3–6	1–3	2–4	1–2	A-I, A-IV, A-V; B-48, C-I, C-II, C-III, E
VLDL	30–70	0.94–1.006	Pre- $\beta$	45–65	15–20	4–8	16–22	6–10	B-100, E, C-I, C-II, C-III
IDL	25–50	1.006–1.019	Broad $\beta$ band	25–35	15–25	4–8	24–35	16–20	B-100, E, C-I, C-II, C-III
LDL	18–30	1.019–1.063	$\beta$	4–8	18–24	6–8	45–50	18–22	B-100
HDL	5–12	1.063–1.21	$\alpha$	2–7	26–32	3–5	15–20	45–55	A-I, A-II, E

VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; TG, triglyceride; PL, phospholipid; %wt, percent by weight.

energy or synthesis is converted to TG (Figure 96-1) through several biosynthetic pathways. TG is a key energy source that is comprised of three fatty acids (FA), each ester-linked to one of the three carbons on a glycerol backbone. TG is synthesized in intestinal epithelial and liver cells, transported through plasma and after lipolysis at the endothelial surface, delivers free fatty acid (FFA) to peripheral cells for  $\beta$ -oxidation, metabolism or storage. Phospholipids (PL) differ from TG by a phosphate ester linked to the third carbon of glycerol. While PLs are biologically important, they do not directly contribute to the main clinical end points associated with dyslipidemia and will not be further considered.

The insolubility of cholesterol and TG in plasma requires that they are transported within spheroidal macromolecules called lipoproteins, which contain PL, fat-soluble antioxidants and vitamins, and cholesteryl

ester (CE) in their hydrophobic core, as well as free cholesterol (C), PL and apolipoprotein (apo) molecules in their hydrophilic coat. Lipoproteins are distinguished by size, density, electrophoretic mobility, composition and function (2) (Table 96-1). The main TG-carrying lipoproteins are the chylomicron (CM) and very-low-density lipoprotein (VLDL). The main cholesterol-carrying lipoproteins are low-density lipoprotein (LDL) and high-density lipoprotein (HDL). Intermediate-density lipoprotein (IDL), physiologically an evanescent species, contains roughly equimolar amounts of cholesterol and TG.

Apolipoproteins provide plasma lipoproteins with structural stability and solubility (6). They also serve as ligands for receptors and/or activators for enzymes. Some important apolipoproteins are listed in Table 96-2. Apo B-100 (B100) of VLDL, IDL and LDL (Figure 96-1)

**TABLE 96-2 Summary of Main Apolipoproteins**

Name	Peptide Length (Amino Acids)	Molecular Weight (kilodaltons)	Associated Lipoprotein(s)	Function
A-I	243	28	HDL, CM	Structural component of HDL; activates LCAT; SR-B1 ligand; promotes cholesterol efflux
A-II	77	17	HDL, CM	Structural (HDL); activates HL and LPL
A-IV	396	46	HDL, CM	Activates LCAT; modulates LPL; possibly TG transport
A-V	366	44	CM	Modulates LPL
(a)	Variable	250–800	Lp(a)	Unknown
B-100	4536	540	VLDL, IDL, LDL	Structural component of LDL; ligand for LDLR
B-48	2152	264	CM	Defining protein of intestinally derived particles
C-I	57	6.6	CM, VLDL, IDL, HDL	Inhibits interaction with LDLR and LRP1; LCAT activator
C-II	79	8.9	CM, VLDL, IDL, HDL	LPL modulator
C-III	79	8.8	CM, VLDL, IDL, HDL	LPL inhibitor
E	299	19	CM, VLDL, IDL, HDL	LDLR and LRP1 ligand; cell growth and immune response

CM, chylomicron; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; LCAT, lecithin:cholesterol acyl transferase; HL, hepatic lipase; LPL, lipoprotein lipase; PL, phospholipid; SR-B1, scavenger receptor type B1; LDLR, LDL receptor; TG, triglyceride.

is synthesized in the liver, while apo B-48 (B48) of CM and CM remnants (CMR, [Figure 96-1](#)) is synthesized in the small intestine. Apo B-100 (4356 amino acids) and B-48 (2152 amino acids) are products of the *APOB* gene (7). Apo B-48 mRNA is produced by editing of the apo B-100 mRNA (8), mediated by a 27kDa editase (*APOBEC1*; MIM 600130). Other important apolipoproteins include apo C-II, a cofactor for lipoprotein lipase (LPL), apo E, a ligand for receptor-mediated endocytosis (RME) and apo A-I, an activator of the enzyme lecithin:cholesterol acyl transferase (LCAT) (3).

Thus, lipoprotein metabolism is a complex and partially understood network of assembly, secretion, processing and catabolism ([Figure 96-1](#)). This chapter will focus primarily on genetic disorders that affect the concentrations of two plasma lipoproteins, namely, LDL and HDL, and one plasma lipid, namely, TG, which have been connected to CVD and related disorders.

## 96.3 LIPOPROTEIN METABOLISM

### 96.3.1 Low-Density Lipoprotein (LDL) Metabolism

Sterols, such as cholesterol and plant sterols in the intestinal lumen enter enterocytes via the Niemann–Pick C1-like 1 (NPC1L1) transporter (9). Plant sterols and some cholesterol are resecreted by heterodimeric ATP-binding cassette transporter G5/G8 (*ABCG5/G8*) (10). Within enterocytes, free cholesterol (C in [Figure 96-2](#)) is packaged with TG into CMs. Within hepatocytes, cholesterol is recycled or synthesized de novo from acetyl coenzyme A (CoA) (Ac, [Figure 96-1](#)) by a multistep synthetic pathway, with the last committed step catalyzed by 3-hydroxy-3-methylglutaryl CoA reductase (11). Free cholesterol can also be (re-)esterified to CE ([Figure 96-1](#)) by an acyl CoA:cholesterol acyltransferase (ACAT,

[Figure 96-1](#)) (12), for incorporation into cytosolic lipid storage droplets or lipoprotein assembly. Lipoprotein-derived CE can be hydrolyzed to release free cholesterol by lysosomal CE hydrolase (CEH, [Figure 96-1](#)), also called lysosomal acid lipase (LAL), and a distinct neutral CEH hydrolyzes cytoplasmic CE (13). Hepatic free cholesterol can be diverted to the BA ([Figure 96-1](#)) synthetic pathway by hydroxylation, for which cholesterol 7- $\alpha$ -hydroxylase (CYP7A1, [Figure 96-1](#)) is rate limiting (14). Most cholesterol that is transported through the circulation in lipoproteins is esterified, with free cholesterol constituting a relatively minor fraction.

The microsomal TG transfer protein (MTP, [Figure 96-1](#)) in hepatocytes directs the assembly of CE and TG together with apo B-100 and apo E to produce VLDL ([Figure 96-1](#) and [Table 96-1](#)) for secretion into plasma (15). VLDL in plasma is lipolytically remodeled into LDL, which is the main cholesterol-carrying lipoprotein since ~70% of total plasma cholesterol is partitioned into LDL ([Figure 96-1](#)). LDL transports cholesterol from the liver to the periphery (16). LDL is actually a spectrum of particles whose main lipid is CE, and whose defining protein moiety is a single molecule of apo B-100 ([Table 96-1](#)). LDL has a plasma half-life of ~3 days, and is cleared by the binding of apo B-100 to peripheral and hepatocyte low-density lipoprotein receptors (LDLRs) ([Figure 96-1](#)), clustering in coated pits, internalized by RME, assisted by an adaptor protein (LDLRAP) (16). Proprotein convertase subtilisin/kexin type 9 (PCSK9) appears to be secreted into plasma, then reenters the cell, complexes with the LDLR and short-circuits recycling of the receptor from the endosome. After RME, apo B-100-containing lipoproteins are processed through lysosomes, and freed cholesterol enters the cellular pool. As hepatic free cholesterol levels increase, LDLR transcription is suppressed, RME is reduced and plasma LDL rises.

**FIGURE 96-2** Frequency distribution of fasting plasma TG concentrations in a population-based sample of more than 22,000 people from Canada. White bars represent male subjects, black bars represent female subjects. Subjects with plasma TG concentration  $>3.37$  mmol/L are in the 95th percentile, considered the threshold for HTG. The maximum plasma TG concentration in this sample was 45 mmol/L.

### 96.3.2 High-Density Lipoprotein (HDL) Metabolism

“Reverse cholesterol transport” (RCT) describes cholesterol transport in HDL from peripheral cells back to the liver for secretion in bile (17). The initial step in HDL metabolism involves the formation of small lipid-poor nascent HDL particles in the liver and small intestine. Nascent HDL particles (Figure 96-1) attract excess free cholesterol from both extrahepatic cells and other circulating lipoproteins. Within peripheral cells, ACAT and CEH (Figure 96-1) maintain the balance between free cholesterol and CE (18). These small HDL particles, via apo A-I (A1, Figure 96-1), mediate RCT by interacting with ABCA1, which directs transfer of CE, and ABCG1, which directs transfer of free cholesterol, transporters on nonhepatic cells (18). Using apo A-I as a cofactor, LCAT esterifies cholesterol for packaging into HDL, which after remodeling by cholesterol ester transfer protein (CETP) and by endothelial lipase (LIPG) enters hepatocytes via scavenger receptor class B type I (SR-B1) (19). SR-B1 mediates the selective uptake of cholesterol ester and other lipids. The receptor, present on hepatocytes, binds to HDL and other lipoproteins, mediating the transfer of cholesterol from serum HDL to the bile for excretion, completing the cycle of RCT and removal of cholesterol from the body (20). The final step in plasma HDL metabolism involves the clearance of apo A-I and pre  $\beta$ -1 HDL in the kidney and excretion in the urine.

In addition to RCT, HDL might (1) suppress cytokine-induced adhesion of endothelial cells; (2) protect LDL from oxidation; and (3) have anticoagulant effects (21). In research laboratories, HDL particles can be subfractionated according to size and density by ultracentrifugation and gradient electrophoresis (22). They can also be separated according to protein content using immunological assays (23); these specialized methods are beyond the reach of most clinical laboratories.

### 96.3.3 Triglyceride (TG) Metabolism

In the intestine, dietary fat is processed prior to absorption (24). For instance, pancreatic lipase hydrolyzes dietary TG to liberate FFAs that are absorbed both passively and actively. BA (Figure 96-1) from liver is secreted and subsequently reabsorbed through specific mediators (25). BA permits absorption of luminal free cholesterol (Figure 96-1). Hydrolyzed dietary fats enter enterocytes via FA transporters. Within enterocytes, processing by ACAT and TG biosynthetic pathways prepare CE and TG, respectively, for MTP-mediated assembly with apo B-48 and apo E through a vesicular pathway into CM, which is the main lipoprotein carrying fat of exogenous origin secreted into the lymph and plasma (26).

CMs secreted into lymphatics enter the vena cava and circulate until they interact with LPL, whose secretion

depends on lipase maturation factor-1 (LMF1, not shown in Figure 96-1) (27), and which is transported to the intestinal lumen by glycosylphosphatidylinositol-anchored HDL-binding protein 1 (GPIHBP1, not shown in Figure 96-1) (28) and secured to endothelium by proteoglycans. CMs contain apo A-V (A5), apo C-II (C2) and apo C-III (C3), among others. Liberated FFAs incompletely enter peripheral cells.

Within adipocytes, enzymes including acyl CoA: diacylglycerol acyltransferase resynthesize TG, which is hydrolyzed by adipose TG lipase and hormone-sensitive lipase. Within the capillaries of adipose tissue and muscle, CM and VLDL core TG are hydrolyzed to FFA by endothelial-bound LPL (Figure 96-1) using apo C-II as a cofactor (C2, Figure 96-1) (29). FFA is reesterified and stored as TG in fat cells, or oxidized to provide energy in muscle. CM and VLDL are remodeled into the short-lived smaller, denser, more CE-rich CMR (Figure 96-1) and IDL (Figure 96-1), respectively (30). CMR and some IDL are cleared by apo E-mediated endocytosis through hepatic remnant receptors (LRP1, Figure 96-1), contributing to the hepatic CE pool (Figure 96-1). IDL that is not cleared is then hydrolysed by hepatic lipase (HL) (Figure 96-1) making smaller, CE-rich LDL particles (Figure 96-1).

### 96.3.4 Plasma Lipoproteins and Cardiovascular Disease Risk

Plasma lipid and lipoprotein concentrations generally follow a right-skewed normal distribution in the general population (Figure 96-2) (3). Median levels vary by age and sex: in general, older age and male sex are associated with a less favorable lipid profile. There are also differences in median levels across geographical ancestries and these might contribute to differences in CVD risk (1). Epidemiologically, CVD is directly related to plasma levels of total and LDL cholesterol (31) and inversely related to plasma levels of HDL cholesterol (32). In men, a rise in total cholesterol from 5.2 to 6.2 mmol/L (200 to 240 mg/dL) is associated with a threefold increased risk of death from coronary heart disease (CHD) (33). HDL cholesterol <0.9 mmol/L (<35 mg/dL) is an independent CHD risk factor and the most common lipid disturbance seen in CHD patients under 60 years of age (34). While the inverse association between HDL and CVD is indisputable, a causal relationship remains uncertain, in part because not all genetic disorders causing very low HDL are associated with the presence of CVD, in contrast to the uniform presence of CVD in genetic disorders causing high LDL. Plasma LDL cholesterol and apo B concentrations are directly correlated (35), as are plasma HDL cholesterol and apo A-I concentrations (36). The ratio of apo B to A-I has been advocated as the strongest predictor of CHD risk (37) but the ratio of total cholesterol to HDL cholesterol seems equally predictive (38). Although the

relationship between plasma TG and CHD has been confounded by the association of elevated TG with depressed HDL cholesterol, elevated TG, especially nonfasting TG (39) and familial HTG (40) are independently associated with CHD risk (41).

A chronic excess of LDL in plasma alters physiological arterial endothelial dilation, which is an early manifestation of vascular dysfunction (42). LDL that does not undergo regulated RME is taken up in an unregulated manner by scavenger receptors, such as CD36 and SRA-I/II, on arterial wall macrophages (43). Entrapped LDL lipids can become oxidized, generating toxic intermediates that induce cytokine production and chemotaxis of inflammatory cells (44). Arterial wall macrophages can become engorged with cholesterol from LDL, creating foam cells, which are a key component of atherogenic plaques (21). Lipids engulfed by macrophages become oxidized, generating toxic intermediates, which induce cytokine production and inflammatory cell chemotaxis (21,44). Occlusive plaques, often the result of rupture compounded by thrombosis, result in CVD, such as CHD or stroke (21,44).

## 96.4 MONOGENIC DISORDERS OF LIPOPROTEIN METABOLISM

Several important genetic determinants of lipoprotein levels have been identified through studies of monogenic disorders (Table 96-3) (3). Monogenic disorders comprise a rare patient subgroup found at the extremes of population-specific lipoprotein distribution. The molecular basis of many monogenic high and low lipoprotein syndromes was elucidated using biochemical approaches or classic genetic linkage analysis. Studies of these diseases have helped define key pathways, such as RME, through the LDLR and sterol efflux from cells via ATP-binding cassette proteins (45). Several causative genes with rare mutations have resurfaced as loci with common small-effect genetic variants that underlie lipoprotein variation in population studies. Many of these disorders are autosomal recessive, due to homozygous mutations in causative genes. Importantly, some affected patients are compound heterozygotes, a category hereafter implicitly included whenever the term “homozygous” is used.

Some of the classic Fredrickson, also called World Health Organization (WHO), hyperlipoproteinemia (HLP) phenotypes have a monogenic basis (Table 96-4) (3). For instance, HLP type 2A is defined by LDL cholesterol >95th percentile of the normal population distribution. However, ~10% of these subjects have a discrete monogenic syndrome (45), such as heterozygous familial hypercholesterolemia (HeFH), or the phenotypically similar disorders familial defective apo B due to binding defects in the *APOB* gene, and autosomal dominant hypercholesterolemia due to gain-of-function (GOF) mutations in the *PCSK9* gene.

The clinical features, molecular genetics, diagnosis and treatment specific to each disorder will be discussed in the following subsections. Later, general approaches to management of dyslipidemia, including diet, lifestyle and pharmacologic classes and individual agents, together with their mechanisms of action, will be discussed in the section on treatment of dyslipoproteinemia.

## 96.5 DISORDERS WITH PRIMARILY ELEVATED LDL CHOLESTEROL

### 96.5.1 Heterozygous Familial Hypercholesterolemia (HeFH)

**96.5.1.1 Clinical Features.** Familial hypercholesterolemia (FH) results from deficiency or defective function of LDLRs (16). FH follows autosomal codominant inheritance, with a very severe phenotype in homozygotes (HoFH), and a dramatic but less severe phenotype in heterozygotes (HeFH). However, the two forms are usually considered separately because HeFH is relatively common, comprising a substantial proportion of adult lipid clinic patients with twice-normal LDL cholesterol levels who can be managed with pharmacological treatment. In contrast, HoFH is essentially a disorder of children and young adults with four times normal LDL cholesterol levels who require extracorporeal plasma exchange or apheresis.

HeFH has been well studied and reviewed (16,46). Its frequency in the general population is 1 in 500, although it is higher within certain ethnic subgroups such as Afrikaners, Quebecois and Christian Lebanese (46b). The defect in HeFH is loss of the capacity of cells to internalize LDL particles. LDL cholesterol residence time in plasma is prolonged, and the particles undergo oxidation and other modifications. Modified LDL particles are taken up in an unregulated manner by macrophages, and this can lead to clinical manifestations. For instance, cholesterol deposits in the eyelids are called “xanthelasmas.” Cholesterol deposits in connective tissues within and surrounding extensor tendons, especially of the hands and Achilles tendons are called “xanthomas.” Deposits along the corneal margin are called “arcus cornealis” or “corneal arcus.” The most life-threatening deposits are within arteries, leading to premature CHD, stroke and peripheral vascular disease. HeFH is a potent risk factor for early CVD and death if undetected and untreated (47). A study of >1000 pediatric HeFH patients found that 89% had a positive family history of premature CVD (48). The Simon Broome Registry (SBR) prospectively evaluated 526 HeFH patients in the prestatin era; the standardized all-cause mortality rate by the fifth decade in HeFH was increased by more than 100-fold compared to normolipidemic subjects (47).

**96.5.1.2 Molecular Genetics.** HeFH patients have one copy of a mutated *LDLR* gene, which is located on

**TABLE 96-5 DLN Criteria for Diagnosis of Heterozygous Familial Hypercholesterolemia**

<i>Family History</i>	
A) First-degree relative with known premature (<55 years men; <60 years women) coronary and vascular disease	1
B) First-degree relative with known LDL-cholesterol >95th percentile and/or	1
i) First-degree relative with tendon xanthomata and/or arcus cornealis	2
ii) Children <18 years with LDL cholesterol >95th percentile	2
<i>Clinical History</i>	
A) Patient has premature (<55 years men; <60 years women) CHD	2
B) Patient has premature (<55 years men; <60 years women) cerebral or peripheral vascular disease	1
<i>Physical Examination</i>	
A) Tendon xanthomata	6
B) Arcus cornealis in a patient <45 years	4
Biochemical results: LDL-C in mmol/L	
>8.5 (320)	8
6.5–8.4 (250–319)	5
5.0–6.4 (190–249)	3
4.0–4.9 (155–189)	1

A “definite” diagnosis of HeFH can be made if the subject scores >8 points or if DNA analysis documents a mutation in the *LDLR* (or other HeFH) gene. A “probable” diagnosis of HeFH can be if the subject scores between 6 and 8 points.

A “possible” diagnosis of HeFH can be made if the subject scores between 3 and 5 points.

From Reference (52).

chromosome 19p13 and comprises 18 exons (16). As of 2011, >1000 mutations in the *LDLR* gene have been documented worldwide in FH patients, and these mutations have been found in all functional domains of the LDLR protein (49). These are found in the Web sites <http://www.ucl.ac.uk/fh-old/> and [http://www.ucl.ac.uk/ldlr/Current/search.php?select\\_db=LDLR&srch=all](http://www.ucl.ac.uk/ldlr/Current/search.php?select_db=LDLR&srch=all). In addition to single nucleotide mutations, insertion–deletions, copy number variations (50) and splicing mutations (51) have also been reported throughout the *LDLR* gene in HeFH patients.

**96.5.1.3 Diagnosis.** The index of suspicion of HeFH would be raised by (1) elevated plasma total or LDL cholesterol found incidentally; (2) a positive family history for premature onset of symptomatic CHD in a first-degree male relative under age 55 and/or first-degree female relative under age 65 and/or possibly very high total and/or LDL cholesterol; and (3) suggestive physical findings. Patients who develop CVD end points at young ages should be carefully evaluated for HeFH.

The Dutch Lipid Network (DLN) (52) and the SBR (47) have suggested diagnostic criteria for HeFH using various clinical, biochemical and molecular genetic attributes (Tables 96-5 and 96-6). More than 80% of individuals with a DLN score >8 had *LDLR* mutations, a cut point now used to specify individuals with “definite” HeFH (52). The SBR guidelines require documentation

**TABLE 96-6 SBR Criteria for Diagnosis of Heterozygous Familial Hypercholesterolemia**

Criterion	Description
<i>a</i>	TC >7.5 mmol/L (290 mg/dL) in adults or >6.7 mmol/L (260 mg/dL) in children <16 years, OR LDL-C >4.9 mmol/L (190 mg/dL) in adults or >4.0 mmol/L (155 mg/dL) in children <16 years
<i>b</i>	Tendon xanthomas in patients or relatives
<i>c</i>	DNA-based evidence of mutation in <i>LDLR</i> (or other FH genes)
<i>d</i>	Family history of MI before age 50 in grandparent, aunt, uncle or before age 60 in parent, sibling or child
<i>e</i>	Family history of raised TC in parent, sibling or child, or TC documented >7.5 mmol/L (290 mg/dL) in grandparent, aunt or uncle
<i>Diagnosis</i>	
A “definite HeFH” diagnosis requires either criteria <i>a</i> and <i>b</i> or criteria <i>c</i>	
A “probable HeFH” diagnosis requires either criteria <i>a</i> and <i>d</i> or criteria <i>a</i> and <i>e</i>	

of tendon xanthomas, which are very specific for HeFH, but are not clinically apparent in ~30% of HeFH subjects, and often not until the fourth decade of life. There appears to be comparable sensitivity and specificity between the DLN and SBR clinical diagnostic criteria, suggesting that either would be helpful in clinical diagnosis (46b). Biochemical screening of relatives of diagnosed HeFH patients, an approach called “cascade testing” (53), appears to be more effective than other detection strategies, such as population-wide LDL cholesterol testing. The attitudes of HeFH family members toward genetic methods of diagnosis appear to be favorable (54).

**96.5.1.4 Molecular Heterogeneity of Autosomal Dominant Hypercholesterolemia.** Part of the gap in detecting mutations in HeFH is due to genetic heterogeneity (45). For instance, a very similar phenotype called HCHOLAD2 results from a missense mutation in *APOB* affecting the LDLR-binding domain of apo B-100, and accounts for 5–10% of patients with the HeFH phenotype. A rare HeFH subtype called HCHOLAD3 results from GOF mutations in *PCSK9*. A similarly rare FH phenotype with autosomal recessive inheritance is called HCHOLAR1, which results from mutations in *LDLRAP1*. These are discussed later.

**96.5.1.5 Treatment.** Once the diagnosis of HeFH has been made, treatment is relatively straightforward. CVD prevention in HeFH requires a global risk reduction program, focusing on modifiable risk factors, including weight control, prudent diet, moderate exercise, smoking cessation and appropriate control of diabetes and hypertension. The dietary protocol in HeFH minimizes cholesterol intake and replaces saturated fats with unsaturated fats. Consumption of plant sterols and stanols can also reduce plasma LDL-C by ~10%. Since HeFH patients

**TABLE 96-7 NCEP ATP III Revised LDL Cholesterol Goals and Cutoff Points for Intervention in Different Risk Categories**

Risk Category	LDL Cholesterol Goal	Initiate Lifestyle Changes	Consider Drug Therapy
<i>High Risk</i> CHD or equivalent (10 year risk >20%) <sup>a</sup>	<2.59 mmol/L (100 mg/dL) Optimal goal	2.59 mmol/L (100 mg/dL) <1.81 mmol/L (70 mg/dL)	2.59 mmol/L (100 mg/dL)
<i>Moderately High Risk</i> 2+ risk factors (10 year risk 10–19%)	<3.34 mmol/L (130 mg/dL)	3.34 mmol/L (130 mg/dL)	3.34 mmol/L (130 mg/dL)
<i>Moderate risk</i> 2+ risk factors	<3.34 mmol/L (130 mg/dL)	3.34 mmol/L (130 mg/dL)	3.34 mmol/L (130 mg/dL)
<i>Lower Risk</i> 0–1 risk factors (10 year risk 0–9%)	<4.12 mmol/L (160 mg/dL)	4.12 mmol/L (160 mg/dL)	4.9 mmol/L (190 mg/dL) Optional 4.12–4.9 mmol/L (160–189 mg/dL)

<sup>a</sup>Calculated according to the Framingham CHD risk equation.  
Modified from Reference (55).

**TABLE 96-8 Canadian Cardiovascular Society Revised LDL Cholesterol Goals and Cutoff Points for Intervention in Different Risk Categories**

Risk Level	Initiate Treatment If	Primary Target (LDL-Cholesterol)	Alternate Target
High Atherosclerosis Most patients with diabetes FRS ≥20% RRS ≥20%	Consider treatment in all patients	<2 mmol/L OR ≥50%↓ LDL-C	Apo B <0.80 g/L
Moderate	LDL-C >3.5 mmol/L OR LDL-C <3.5 mmol/L AND at least one of: FRS 10–19% TC/HDL-C >5.0 Family history of CVD Metabolic syndrome hs-CRP >2 mg/L in Men >50 years Women >60 years	<2 mmol/L OR ≥50%↓ LDL-C	Apo B <0.80 g/L
Low	LDL-C ≥5.0 mmol/L	≥50%↓ LDL-C	

FRS, Framingham risk score 10-year CVD risk; RRS, Reynolds risk score 10-year CVD risk; LDL-C, low-density lipoprotein cholesterol level; apo B, apolipoprotein B level; TC, total cholesterol level; HDL-C, high-density lipoprotein cholesterol level; hs-CRP, plasma C-reactive protein measured using a high-sensitivity assay. Adapted from Reference (124).

would be considered to be at high risk, treatment targets for LDL-C should follow those advised in national clinical treatment guidelines (Tables 96-7 and 96-8) for patients at high risk (55).

Pharmacotherapy is very frequently required in HeFH patients because the plasma LDL cholesterol targets usually cannot be reached with diet and lifestyle changes alone. Currently available agents for management of dyslipidemia are shown in Table 96-9. Statins—HMG-CoA reductase inhibitors—are the agents of first choice in HeFH. Statins deplete liver cholesterol content, which upregulates LDLR expression and results in increased removal of LDL from plasma. Subjects with HeFH have one normal LDLR allele to upregulate. Plasma LDL

cholesterol reductions of ~50% can be achieved with higher dose statin monotherapy (56). HeFH patients generally require more than one medication to reach guideline LDL cholesterol targets. Ezetimibe, a cholesterol absorption inhibitor that is well tolerated, is now increasingly used in combination with statins in individuals who require large absolute and relative reductions in plasma LDL cholesterol, such as those with HeFH (57). When used in combination with a statin, a further decrease in plasma LDL cholesterol of 18–25% was seen with ezetimibe (57). Other agents such as bile acid sequestrants (BAS) and niacin preparations can also be used as part of combination therapy regimens to lower plasma LDL cholesterol in HeFH (58).

**TABLE 96-9** Classes of Available Drugs for Managing Dyslipidemia

Type of Drug	Mechanism of Action	Major Effects	Example(s)	Adverse Reactions
HMG CoA reductase inhibitors (statins)	Inhibits cholesterol synthesis in hepatic cells, resulting in upregulation of hepatic LDL receptors	Lowers LDL-C and TG	Atorvastatin, lovastatin, pravastatin, simvastatin, fluvastatin, rosuvastatin	Raised hepatic enzymes, raised serum creatine kinase, myopathy possibly progressing to rhabdomyolysis
BA-binding resins	Binds intestinal BAs interrupting enterohepatic recirculation, which in turn results in LDL receptor upregulation	Lowers LDL-C, raises TG	Cholestyramine, colestipol, colesevelam	Limited to gastrointestinal tract: gas, bloating, constipation, cramps
Fibric acid derivatives	Probably inhibits hepatic synthesis of VLDL; stimulates LPL	Mainly lowers TG and raises HDL-C, less effect on LDL-C	Gemfibrozil, fenofibrate, bezafibrate, ciprofibrate	Dyspepsia, constipation, myositis, anemia
Nicotinic acid (extended release)	Upregulates hepatic LDL receptors	Lowers TG and LDL-C	Niacin	Flushing, hepatic toxicity
Cholesterol absorption inhibitors	Inhibits intestinal absorption of cholesterol and plant sterols	Lowers LDL-C	Ezetimibe	Myopathy, gastrointestinal upset
Omega-3 fatty acids (fish oils)	Reduce hepatic secretion of VLDL	Lower TG	Omacor (R), Lovaza (R)	Gastrointestinal discomfort; flulike symptoms

HMG CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; LDL, low-density lipoprotein; LDL-C, LDL cholesterol level; VLDL, very-low-density lipoprotein; TG, triglyceride; HDL-C, high-density lipoprotein cholesterol level.

Drug treatment of HeFH is very cost-effective: in primary CHD prevention, statin treatment for 10 years saves both lives and money in HeFH men aged 35–44 with no additional risk factors, and in HeFH women aged 35–44 with at least one additional risk factor (59). Cascade testing to detect new HeFH patients followed by statin treatment prevented 26 myocardial infarctions for every 100 persons aged 20–60 treated for 10 years, gaining a mean of 3.3 years of life for each patient so detected and treated (60). The total lifetime cost for screening and testing, lifetime drug treatment and treatment of CHD events was ~US\$9000 per new case detected and the cost per life-year gained was ~US\$10,000 (60), while the cost per death avoided over 10 years using cascade testing followed by statin treatment was ~US\$7000 (61).

A common clinical concern is CHD prevention when HeFH has been diagnosed in children or adolescents (62). A recent approach to treat children with genetically elevated LDL cholesterol has been proposed (Table 96-10). Dietary and lifestyle advice form the therapeutic cornerstone. Drug treatment of pediatric HeFH is an evolving field because there are few long-term data (63). There are advocates for the idea of initiating treatment at a very young age and maintaining treatment over a patient's lifetime (64). BAS have the advantage of not being systemically absorbed, but they are poorly tolerated. Tolerability is also an issue with short-acting niacin preparations. Ezetimibe has theoretical advantages, but is currently not indicated in children or adolescents. The exact age to initiate treatment and the applicability of adult targets in children are uncertain. Referral for specialist opinion remains a very appropriate option for children and adolescents with HeFH.

### 96.5.2 Familial Defective Apo B (Autosomal Dominant Hypercholesterolemia Type 2)

A minority of patients with a clinical and biochemical diagnosis of HeFH actually have autosomal dominant FH type 2 (ADHCHOL2), also called familial defective apo B (FDB) resulting from one of several possible mutations within the LDLR-binding domain of the apo B-100 protein, of which the most recurrent is R3537Q (formerly R3500Q) (65). These apo B-100 mutants exhibit only a small percentage of normal receptor-binding activity. The APOB R3537Q mutation has a population frequency of ~1/1000 in Europeans (66). The severity of the phenotype due to a heterozygous mutation in APOB is often less severe than with a heterozygous mutation in the *LDLR*: heterozygous FDB individuals exhibit LDL cholesterol levels of ~6 mmol/L (~240 mg/dL) (67). Homozygous FDB presents with biochemical, clinical and CAD risk profiles similar to HeFH, while heterozygous FDB is generally less severe than HeFH in all of these respects; for instance, tendinous xanthomas are uncommon in FDB (68). Treatments used in HeFH are also usually effective in FDB (68,69). In contrast to HoFH, homozygous FDB patients respond to statin therapy (67).

### 96.5.3 PCSK9 Gain-of-Function Mutations (Autosomal Dominant Hypercholesterolemia Type 3)

A third molecular form of autosomal dominant hypercholesterolemia (ADHCHOL3) was shown by linkage

**TABLE 96-10 Recommendations for Drug Treatment of High-Risk Children with Dyslipidemia**

1. Consider drug therapy in children 10 years of age (usually wait until menarche for females) and after a 6- to 12-month trial of fat- and cholesterol-restricted dietary management
2. Consider drug therapy if LDL cholesterol level remains >4.90 mmol/L (190 mg/dL) or >4.10 mmol/L (160 mg/dL) and there is a positive family history of premature CVD, or if two other risk factors are present in the child or adolescent after vigorous efforts to modify these risk factors
3. Referral to specialized lipid center may be deemed appropriate
4. Treatment goals:      Minimal LDL cholesterol <3.35 mmol/L (130 mg/dL) Ideal LDL cholesterol <2.85 mmol/L (110 mg/dL)
Other considerations
1. In addition to family history, overweight and obesity should trigger screening with a fasting lipid profile
2. Overweight and obese children with lipid abnormalities should be screened for other aspects of the metabolic syndrome (i.e. insulin resistance and type 2 diabetes, hypertension, or central adiposity).
3. A statin is recommended as first-line treatment when drug treatment is deemed appropriate.
4. For children with high-risk lipid abnormalities, the presence of additional high-risk conditions may also result in adjustment of the LDL cholesterol level for initiation of drug therapy, the target LDL cholesterol level, and may prompt consideration for initiation below the age of 10 years
5. High-risk conditions may include
Male gender
Strong family history of premature CVD or events
Presence of associated low HDL, high triglycerides, small dense LDL
Presence of overweight or obesity and aspects of the metabolic syndrome
Presence of medical conditions such as diabetes, HIV infection, systemic lupus erythematosus, organ transplantation
Presence of hypertension
Current smoking and passive smoke exposure
Presence of novel and emerging risk factors and markers, e.g. elevated Lp(a), C-reactive protein

Adapted from Reference (62).

mapping to be due to heterozygous GOF mutations in *PCSK9*. This disorder displays many features of HeFH (70), although such patients comprise <1% of patients with a clinical diagnosis of HeFH referred to most lipid clinics. They can generally be managed in the same manner as patients with heterozygous *LDLR* mutations (49,71).

## 96.5.4 Homozygous Familial Hypercholesterolemia (HoFH)

**96.5.4.1 Clinical Features.** The classic clinical manifestations of HoFH include early appearance of corneal arcus, cutaneous planar xanthomata over hands and extremities, tuberous xanthomata over elbows, interphalangeal joints, knees, and tendinous xanthomata in the hand extensor and Achilles tendons, although xanthelasmata appear to be more common in HeFH patients (16,72). In HoFH, these signs may become manifest in the first or second decade of life, compared to the third to fifth decade in HeFH patients. HoFH children are predisposed to early atherosclerosis, including arterial plaque formation and coronary ostial stenosis leading to cardiac ischemia (72). With prolonged plasma exchange or LDL apheresis, vascular calcification, especially of the aortic root, has emerged as a significant clinical issue (73). Aortic valvular thickening and aortic root disease can lead to aortic regurgitation (74) or stenosis (72) requiring valve replacement. Death from myocardial infarction occurs in untreated subjects before age 30 (16,47), although disease progression in individual patients is variable (75).

**96.5.4.2 Molecular Genetics.** Children with HoFH inherit two defective copies of the *LDLR* gene and thus lack functional LDLRs, resulting in plasma LDL concentrations elevated on average sixfold above the normal range (76). Parents of HoFH children have HeFH, with one defective and one wild-type *LDLR* allele each. HoFH has a prevalence of 1 in 1,000,000 in most populations, with higher frequencies in founder populations (16).

**96.5.4.3 Diagnosis.** Diagnosis of HoFH is based on a combination of physical and biochemical findings, family history and molecular genetic analysis (77). Clinicians should suspect HoFH in children presenting with these physical signs and a positive family history of HeFH in one or both parents. Conversely, isolated pediatric HoFH may indicate undiagnosed parental HeFH (78). Serum lipid profiling for both parents and their children is indicated. HoFH children have plasma total cholesterol levels >10 mmol/L (>390 mg/dL) and often >18 mmol/L (>700 mg/dL); HoFH should thus be suspected in children when plasma cholesterol levels exceed these thresholds (79). For HeFH in patients <16 years old, the SBR criteria (47) specify a total plasma cholesterol >6.7 mmol/L (>260 mg/dL) or plasma LDL cholesterol >4.0 mmol/L (>155 mg/dL) for a positive diagnosis. In contrast, specific diagnostic guidelines for HoFH have not been validated. Definitive diagnosis requires *LDLR* gene sequencing showing mutations within both alleles or *LDLR* functional assays in cultured fibroblasts showing impaired receptor function (16).

**TABLE 96-11 Emerging Treatments for Dyslipidemia**

Name	Company	Mechanism of Action	Indication	Stage	Biochemical Effect
Lomitapide	Aegerion	MTP inhibitor	Hypercholesterolemia	Phase II	Decreases TGs and VLDL
Mipomersen	ISIS/Genzyme	mRNA inhibitor of APOB	HeFH and HoFH	Phase II	Lowers LDL
Dalcetrapib	Roche	CETP inhibitor	Hyperlipidemia	Phase III	Raises HDL
Anacetrapib	Merck	CETP inhibitor	Hyperlipidemia	Phase III	Raises HDL
Niacin/laripoprant	Merck	Prostaglandin D2 inhibitor	Hyperlipidemia	Phase III	Raises HDL cholesterol, decreases TG
Eprotirome	Karo Bio	Thyromimetic	Dyslipidemia	Phase II	Decreases VLDL, LDL, Lp(a)

MTP, microsomal triglyceride transfer protein; APOB, apolipoprotein B gene; CETP, cholesterol ester transfer protein; VLDL, very-low-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; HeFH, heterozygous familial hypercholesterolemia; HoFH, homozygous familial hypercholesterolemia.

**96.5.4.4 Treatment.** Patients with HoFH receive dietary counseling to reduce intake of exogenous cholesterol and saturated fats (80). The current treatment of choice for HoFH is plasmapheresis or LDL-apheresis, which has proved to be highly effective in prolonging end-point free survival (81). LDL-apheresis has the advantages of reduced exposure to blood products, no significant changes in HDL cholesterol levels, and less dramatic volume shifts compared to straight plasma exchange (82). Concurrent high-dose statin therapy may enhance LDL clearance by upregulating the expression of partially functional LDLR, but patients whose mutations leave them with nonfunctional LDLR show little plasma LDL cholesterol response (83). Ezetimibe seems to have some modest efficacy in plasma LDL cholesterol reduction in HoFH (84). Liver transplantation, sometimes together with heart and lung transplantations, and gene therapy have been attempted, with variable results (16,85). Emerging investigational treatments (Table 96-11) for HoFH include biological treatments such as parenteral antisense RNA directed against APOB and the MTP inhibitor class of medications (86).

## 96.5.5 Autosomal Recessive Hypercholesterolemia

**96.5.5.1 Clinical Features.** Autosomal recessive hypercholesterolemia (ARH) has a clinical presentation closely resembling HoFH, with some key differences. For instance, while most physical signs are quite similar, aortic valve stenosis is less common and aortic root disease shows slower progression (87). Age of diagnosis can vary between the first and fifth decades of life, meaning ARH is a potential diagnosis in both pediatric and adult populations. In reported patients, total plasma cholesterol levels have varied between 9.6 and 27.1 mmol/L (370 and 1050 mg/dL), while LDL cholesterol levels have varied between 8.6 and 22.9 mmol/L (330 and 890 mg/dL) (88). Despite the large variability, these parameters are

sufficiently abnormal in ARH patients to satisfy the SBR criteria for HeFH diagnosis; in the context of a severe pediatric clinical presentation ARH closely resembles HoFH (47).

**96.5.5.2 Molecular Genetics.** ARH was mapped by linkage analysis in a family with severe hypercholesterolemia but no mutations in *LDLR* or *APOB*. LDLRAP1 facilitates LDL uptake by hepatocytes by promoting clathrin-pit-mediated LDLR clustering and internalization (89).

**96.5.5.3 Diagnosis.** ARH may be distinguished from severe HeFH or HoFH through sequencing of the *ARH* and *LDLR* genes or through Western blotting of ARH protein in biopsy samples (90).

**96.5.5.4 Treatment.** Treatment of ARH differs substantially from HoFH in that statins reduce plasma LDL cholesterol by 30–60% (91). ARH fibroblasts might employ a different mechanism of LDLR internalization independent of LDLRAP1 protein (89a,92) so that statin-induced LDLR upregulation enhances LDL clearance by these cells. In addition to diet and lifestyle modification, combination therapy including statins, ezetimibe and BAS is typically indicated in these patients (93), without necessarily requiring plasmapheresis or LDL-apheresis.

## 96.6 DISORDERS WITH PRIMARILY DEPRESSED LDL CHOLESTEROL

Abnormally low plasma levels of LDL particles (typically far below 0.5 mmol/L or 20 mg/dL) may be caused by several monogenic disorders. The two best understood are abetalipoproteinemia (ABL) and familial hypobetalipoproteinemia (FHBL), which result from mutations in the *MTP* and *APOB* genes, respectively (69). A rare form of milder FHBL can also result from heterozygous loss-of-function (LOF) mutations in the *PCSK9* gene. Very low plasma TG is also found in patients with chylomicron retention disease (CRD), in addition to low LDL cholesterol, and in some patients with ABL and with FHBL.

### 96.6.1 Abetalipoproteinemia (ABL)

**96.6.1.1 Clinical Features.** At birth, infants with ABL are asymptomatic, but with a high fat diet they can develop gastrointestinal symptoms resembling celiac disease with diarrhea, vomiting and abdominal distension. The gastrointestinal manifestations may later subside, in part because some patients learn to avoid fatty foods (94). Fat-soluble vitamin deficiency develops because plasma transport and delivery depends almost exclusively (for vitamin E and beta-carotene) or in part (for vitamins A, D, and K) on intact synthesis and secretion of apo B-containing lipoproteins. Most reported ABL patients >20 years of age who had not received vitamin supplementation developed neurological and retinal complications. However, there is heterogeneity in disease presentation across patients, which may correlate with the nature and severity of the molecular defect (94).

The initial neurological signs include diminution and loss of deep tendon reflexes followed by progressive sensory loss of proprioception and vibration, development of a spinocerebellar syndrome and muscular weakness. In addition, slowed intellectual development is seen in up to one-third of patients. Neuropathology reveals axonal degeneration of the spinocerebellar tracts and demyelination of the fasciculus cuneatus and gracilis tracts (94). The myopathy results from both neural degeneration and an intrinsic myositis. Although the clinical course is variable without treatment, it leads progressively to impaired mobility, and some patients become wheelchair-bound or bedridden. ABL patients also complain of decreased night and color vision at an early age, followed by a decrease in visual acuity. The visual field shows a concentric contraction. Fundoscopic examination shows pigmentation of the retina. If left untreated, blindness can be present by the fourth decade.

ABL subjects can have hepatosteatosis associated with elevated serum transaminases and sometimes hepatomegaly. Only rarely does this progress to cirrhosis. Acanthocytosis on the peripheral blood film is pathognomonic of ABL. Patients may also have a moderate to severe hemolytic anemia. Abnormalities in coagulation, elevated prothrombin time, caused by deficiency in vitamin K-dependent coagulation factors may lead to bruising or hemorrhage (94). Despite the cholesterol deficiency, steroidogenesis, adrenal function and sexual development are usually normal.

**96.6.1.2 Molecular Genetics.** ABL affects <1 in 100,000 persons. ABL shows autosomal recessive inheritance as obligate heterozygotes have normal plasma lipid levels (94). Missense and truncation mutations in *MTP* (95) that result in nonfunctional protein products cause a near complete lack of circulating apo B-containing lipoproteins in the plasma of homozygotes or compound heterozygotes (96).

**96.6.1.3 Diagnosis.** Most clinical features seen in ABL together with (1) acanthocytosis, (2) the virtual absence

of LDL and apo B containing lipoproteins, and (3) normal LDL cholesterol levels in parents would suggest a diagnosis of ABL. DNA sequence analysis of the *MTP* gene can confirm the diagnosis.

**96.6.1.4 Treatment.** Early diagnosis and treatment are essential to prevent growth retardation and neuro-ophthalmological complications secondary to chronic lipid malabsorption and deficiencies of fat-soluble vitamins. To provide an adequate amount of total calories, the proportion of protein and carbohydrate in the diet must be increased. The lipid-poor diet should also provide the minimal daily requirements of essential FA, often in the form of vegetable oils. Oral medium-chain TGs have been used to provide dietary FA for absorption through the portal circulation, bypassing the MTP defect.

The other mainstay of treatment in ABL is fat-soluble vitamin replacement (94). Vitamin A deficiency is easily compensated for by oral supplementation because after intestinal absorption and transport to the liver, vitamin A has its own lipoprotein-independent transport system, unlike vitamin E. Daily doses two- to fourfold of the normal recommended doses are generally required to normalize the levels of vitamin A or beta-carotene.

Vitamin D deficiency is not classically described in ABL because the metabolism of vitamin D does not depend much on apo B-containing lipoproteins, since there is partial absorption via the portal vein system and specific vitamin D transport proteins. However, the development of rickets and osteomalacia has been reported and therefore prophylactic supplements should be instituted early in life.

ABL subjects require lifetime therapy with vitamin E in large oral doses of 100–300 U/kg/day, which can be absorbed through the portal system; parenteral administration is usually not required. Plasma levels of vitamin E rarely exceed 10–30% of normal even after long-term therapy. Nevertheless, the levels in adipose tissue, hepatic tissue, and erythrocytes almost always increase and sometimes even normalize. Early administration of vitamin E arrests progression of the neuropathy and myopathy (94).

Vitamin K administration either orally or parenterally rapidly corrects defective coagulation.

### 96.6.2 Familial Hypobetalipoproteinemia (FHBL)

**96.6.2.1 Clinical Features.** Homozygous FHBL shares most of the clinical attributes of ABL, with the main distinguishing feature of half-normal plasma concentrations of plasma apo B-containing lipoproteins in heterozygote parents, compared to normal levels in parents of ABL subjects (97). As in ABL, homozygotes may be detected at a young age because of fat malabsorption and reduced plasma total and LDL cholesterol levels.

Heterozygous FHBL patients may be asymptomatic or may experience some of the same symptoms as

homozygous FHBL patients, although these symptoms usually appear during adulthood (96,98). Obligate FHBL heterozygotes have LDL cholesterol concentrations in the lowest tenth percentile, but are typically healthy and usually have little difficulty absorbing fat.

**96.6.2.2 Molecular Genetics.** Homozygous FHBL occurs in <1 in 100,000 persons. FHBL segregates as an autosomal codominant trait. In FHBL, ~60 mutations have been documented in the *APOB* gene (98). These are both truncation mutations and missense mutations that occur outside the LDLR-binding domain of the apo B-100 protein. There is no clear relationship between the type and position of the *APOB* mutation and the severity of the homozygous FHBL phenotype.

**96.6.2.3 Diagnosis.** The clinical features of ABL combined with half-normal LDL cholesterol levels in parents would suggest a diagnosis of homozygous FHBL (97). Sequence analysis of the *APOB* gene can confirm the diagnosis.

**96.6.2.4 Treatment.** The treatment of homozygous FHBL is similar to that of ABL. No specific treatment is indicated for heterozygotes, but dietary supplementation with fat-soluble vitamins, especially vitamin E, is reasonable.

### 96.6.3 PCSK9 Loss-of-Function Mutations

**96.6.3.1 Clinical Features.** While screening individuals with very low LDL cholesterol as a contrast group for sequencing the *PCSK9* gene to detect GOF mutations in individuals with very high LDL cholesterol (70), novel heterozygous mutations were found in the low LDL contrast group (99). These were shown to be LOF mutations in *PCSK9*, indicating that, like mutations in *APOB*, different types of mutations in *PCSK9* produce opposite extremes of the LDL cholesterol phenotype. While heterozygotes for *PCSK9* LOF mutations only had low total and LDL cholesterol and apo B, they had no other specific physical findings. Individuals of several ancestries who had heterozygous LOF mutations in *PCSK9* had significant lifelong protection against atherosclerosis: heterozygous nonsense mutations and nonsynonymous sequence variations in *PCSK9* appear to reduce CVD risk by up to 88% (100). Rare individuals with two LOF *PCSK9* alleles had extremely low but detectable plasma apo B and LDL cholesterol (101), which contrasts with the undetectable levels of these measurements typical of ABL and homozygous FHBL.

**96.6.3.2 Molecular Genetics.** The *PCSK9* gene encodes proprotein convertase subtilisin/kexin 9, a serine protease that enhances LDLR degradation following both biosynthesis and LDL-mediated internalization; *PCSK9* function negatively correlates with LDLR expression and positively correlates with plasma LDL concentration (102). There is no obvious relationship between the type and position of the

mutation in *PCSK9* and the severity of the clinical phenotype.

**96.6.3.3 Treatment.** No specific treatment is considered necessary for patients with LOF mutations in *PCSK9*.

### 96.6.4 Fat Malabsorption Disorders

**96.6.4.1 Clinical Features.** Patients with CRD, also known as Anderson disease, resemble those with ABL with respect to dietary fat malabsorption and its consequences. These patients are able to synthesize the full-length apo B-100 in the liver, but cannot synthesize intestinal apo B-48. The intestinal transcription of apoB-100 mRNA and its editing to apoB-48 mRNA proceed normally. Both apo B and dietary TG are found in enterocytes. Nevertheless, CMs are not secreted (103). Affected children present with steatorrhea and diarrhea within the first few days of life, and failure to thrive becomes apparent after a few months (104). Plasma LDL cholesterol and the BA pool are markedly decreased, while fecal BA content and total stool output are markedly increased (104a,105).

**96.6.4.2 Molecular Genetics.** The causative gene for CRD is *SAR1B*, encoding a member of the small GTPase family called COPII, which governs the intracellular trafficking of proteins in coat protein-coated vesicles. Rare coding sequence mutations were seen in all affected patients (106), indicating that *SAR1B* is the causative gene for a spectrum of related disorders. Mechanistically, it would appear that the apo B-48 isoform interacts with the gene product to engage the COPII transport machinery as part of the mechanisms of CM secretion.

**96.6.4.3 Treatment.** The general treatment regimen follows that recommended for ABL and HHBL (homozygous familial hypobetalipoproteinemia), including fat restriction and fat-soluble vitamin supplements.

### 96.6.5 Primary Bile Acid Malabsorption

The *SLC10A2* gene (MIM 601295) encodes the apical sodium-dependent bile acid transporter, which has an important role in BA reabsorption in the distal ileum (107). Certain splicing and missense mutations in *SLC10A2* have reportedly caused primary BA malabsorption in children who are homozygotes or compound heterozygotes for these rare mutant *SLC10A2* alleles (104a). Patients have low plasma LDL cholesterol, although data on long-term CVD risk are lacking. Steatorrhea and diarrhea improve dramatically through dietary therapy that is low in TG and high in medium-chain FA (104a).

## 96.7 DISORDERS WITH PRIMARILY ELEVATED HDL CHOLESTEROL

A few individuals with HDL cholesterol >95th percentile, also termed “hyperalphalipoproteinemia,” have mutations causing deficiencies of CETP or SR-B1 (molecular

alias *SCARB1*) (108). In addition, some LOF mutations in *LIPG* encoding endothelial lipase (EL) are associated with elevated HDL cholesterol levels.

### 96.7.1 Cholesteryl Ester Transfer Protein (CETP) Deficiency

**96.7.1.1 Clinical Features.** CETP deficiency leads to the accumulation in plasma of CE-rich large HDL, with resulting elevations in plasma concentrations of HDL cholesterol and apo A-I and reductions in plasma LDL cholesterol and apo B (17). There are no specific physical manifestations associated with CETP deficiency. The impact of genetic CETP deficiency on CVD risk is controversial, especially after a clinical trial with torcetrapib, a CETP inhibitor, caused an unexpected increase in cardiac deaths (109). CETP deficiency might be a state of impaired RCT, which may lead to atherosclerosis despite high plasma HDL cholesterol levels (110).

**96.7.1.2 Molecular Genetics.** Genetic deficiency of CETP is caused by mutations in the *CETP* gene (111). Genetic CETP deficiency is relatively common in Japanese subjects with elevated plasma HDL cholesterol: several CETP mutations have been identified in the Japanese population and these appear to be associated with protection from atherosclerosis (17). However, in Caucasian populations, elevated HDL cholesterol due to mutant *CETP* seems to be rare and inconsistently associated with CVD risk (112).

**96.7.1.3 Treatment.** No specific treatment is indicated in CETP deficiency. Global CVD risk should be assessed and preventive treatments used, especially in the presence of multiple risk factors other than low HDL cholesterol.

### 96.7.2 Scavenger Receptor B1 (SR-B1) Deficiency

**96.7.2.1 Clinical Features.** DNA sequencing of individuals with very high plasma HDL cholesterol identified a family with a missense mutation in *SCARB1*, altering the amino acid sequence: P297S (113). Heterozygotes had mean HDL cholesterol that was increased by ~50% over noncarriers. The lipid profile was otherwise normal, as was CVD risk. Platelets from carriers had increased unesterified cholesterol content and impaired function. In addition, adrenal steroidogenesis was attenuated, with decreased urinary excretion of sterol metabolites, decreased response to corticotropin stimulation, and symptoms of diminished adrenal function (113).

**96.7.2.2 Molecular Genetics.** High HDL cholesterol segregated as an autosomal dominant trait in *SCARB1* mutation carriers; the mutant had diminished function in vitro (113). Carriers also had a reduced capacity to efflux cholesterol in vivo.

**96.7.2.3 Diagnosis.** The constellation of increased HDL cholesterol together with abnormalities of platelet

function and adrenal steroidogenesis might indicate an individual whose *SCARB1* gene could be sequenced.

**96.7.2.4 Treatment.** No specific treatment for the lipoprotein disturbance is indicated. Reduction in CVD risk—management of blood pressure, diabetes, and obesity, with smoking cessation—should be strongly considered.

### 96.7.3 Loss-of-Function Variants in *LIPG* Encoding Endothelial Lipase (EL)

*LIPG* LOF mutations were found in asymptomatic individuals with elevated plasma concentrations of HDL cholesterol (114). There are no obvious clinical symptoms or physical findings associated with the biochemical findings; in particular, the association with atherosclerosis or CVD is unclear. Among individuals with elevated HDL cholesterol, in vitro lipase activity assays demonstrated that most were LOF variants with decreased EL activity (114). The *LIPG* N396S LOF variant, which has a population frequency between 1 and 5% and significantly decreased lipase activity, was associated with increased HDL cholesterol. Diagnosis of EL deficiency is based primarily on DNA sequence analysis. No specific treatment for the lipoprotein disturbance is indicated.

## 96.8 DISORDERS WITH PRIMARILY DEPRESSED HDL CHOLESTEROL

Several genetic disorders lead to reduced plasma HDL cholesterol, including mutations in *ABCA1*, *LCAT* and *APOA1*. In addition, glucocerebrosidase mutations in Gaucher disease, type 1 (GD1; MIM 230800), are associated with low HDL (115). Finally, a subtype of Niemann–Pick disease is associated with very low HDL (116), reinforcing the role of Niemann–Pick type C protein (NPC1; MIM 257220) in intracellular cholesterol transport. Criteria for the definition of familial hypoalphalipoproteinemias are (1) a low HDL cholesterol level in the presence of normal VLDL cholesterol and LDL cholesterol levels, (2) an absence of conditions in which low HDL cholesterol may be secondary, and (3) the presence of a similar lipoprotein pattern in a first-degree relative.

### 96.8.1 Tangier Disease

**96.8.1.1 Clinical Features.** Tangier disease (TD) is characterized by the presence of orange tonsils, splenomegaly, discoloration of the rectal mucosa, hepatomegaly, corneal opacities, premature CHD, and peripheral neuropathy that may be either transient and recurring or progressive and debilitating. Biochemically, TD is characterized by a near absence of HDL particles (<0.05 mmol/L or <2 mg/dL) (117) and very low plasma apo A-I levels. HDL catabolism is accelerated and in vitro efflux of cholesterol and PL from fibroblasts is impaired (118). CHD risk appears to be increased in

TD homozygotes and heterozygotes, perhaps because of concurrent presence of low LDL cholesterol levels on occasion (119). Some TD patients also have mild HTG.

**96.8.1.2 Molecular Genetics.** TD is caused by homozygous mutations of the *ABCA1* gene (120), whose product plays a focal role in cholesterol efflux from the cell interior onto nascent HDL particles via apo A-I (121). CE becomes deposited in the reticuloendothelial system. TD mutations probably impair the ability of cell surface *ABCA1* transporters to transfer cholesterol to HDL and the lipid-poor HDL is more prone to catabolism (122).

**96.8.1.3 Treatment.** TD has no specific treatment; currently available HDL-raising drugs are minimally effective (123). Thus a reasonable treatment strategy later in life is to improve the plasma LDL:HDL ratio using LDL-lowering pharmacotherapy in combination with CVD risk factor reduction and prevention through lifestyle and diet modification (124). Treatment is guided by the presence of secondary conditions and complications.

## 96.8.2 Lecithin:Cholesterol Acyl Transferase (LCAT) Deficiency States

**96.8.2.1 Clinical Features.** Two kinds of genetic LCAT deficiencies have been reported. The first is complete LCAT deficiency, which is characterized by anemia, increased proteinuria and renal failure (125). The second is partial LCAT deficiency, also called fish-eye disease (FED) (126). Both disorders are characterized by progressive corneal opacification, very low plasma HDL cholesterol (usually  $<0.25$  mmol/L or  $<10$  mg/dL), and variable HTG. Complete LCAT deficiency is also characterized by abnormal lipid deposition in tissues, normochromocytic anemia, renal disease and variable presentation of early CVD (127).

**96.8.2.2 Molecular Genetics.** Approximately 30 kindreds and numerous LCAT mutations have been reported worldwide: these comprise ~60 patients with complete LCAT deficiency and ~20 patients with FED (128). Deficiency of LCAT prevents the normal esterification of cholesterol that is necessary in the life cycle of the developing HDL particle. There is no consistent relationship between the nature of the LCAT mutation or its position within the coding sequence and the clinical and biochemical subphenotypes of either familial LCAT deficiency or FED. LCAT deficiency is inconsistently associated with an increased risk of CHD (128).

**96.8.2.3 Diagnosis.** In the presence of extremely low plasma HDL cholesterol, additional signs such as corneal clouding, tendon or skin-fold xanthomata and, in some cases, premature CVD during adulthood should trigger consideration of possible LCAT deficiency (129). The diagnosis of LCAT deficiency could be made based on the quantification of plasma cholesterol esterification activity, performed in specialized laboratories; however, the LCAT gene can also be sequenced.

**96.8.2.4 Treatment.** LCAT deficiency has no specific treatment; currently available drugs are minimally

effective at raising HDL cholesterol. A reasonable treatment strategy is to improve the plasma LDL:HDL ratio using LDL-lowering pharmacotherapy in combination with CVD risk factor reduction and prevention through lifestyle and diet and management of complications, such as renal transplantation for end-stage renal disease (129).

## 96.8.3 Apolipoprotein A-I Deficiency

**96.8.3.1 Clinical Features.** Homozygosity for some *APOA1* mutations affects the assembly of HDL, and has been found in patients with very low HDL cholesterol, xanthomas and early CHD (128). Heterozygotes for mutant apo A-I often have less severe reductions in HDL cholesterol ( $<0.25$  mmol/L or  $<10$  mg/dL). Other than corneal opacities and occasional xanthomas, most patients exhibit no clinical sequelae. Certain *APOA1* missense mutations, e.g. apo A-I Iowa (G26R) cause systemic amyloidosis; mutant protein is found within amyloid plaques, but these mutations have no impact on plasma HDL cholesterol levels or CVD risk (130).

**96.8.3.2 Molecular Genetics.** Approximately 30 mutations involving the *APOA1* gene have been reported (128), including (1) large deletions that disrupt *APOA1* plus neighboring genes in the *APOA1/C3/A4/A5* gene cluster on chromosome 11, (2) nonsense or splicing mutations or deletions that affect *APOA1* specifically, and (3) missense mutations affecting the coding sequence of *APOA1*. In general, plasma HDL cholesterol is almost undetectable in persons with deletions or nonsense mutations of the *APOA1* gene. In contrast, HDL cholesterol levels are detectable (usually 0.3–0.6 mmol/L or 10–20 mg/dL) with some missense mutations in *APOA1*. For instance, patients with *APOA1* Milano, inherited as an autosomal dominant trait, have low but detectable HDL levels, but do not have an increased risk of premature CVD (131).

**96.8.3.3 Diagnosis.** The molecular diagnosis can be made by DNA sequence analysis or by plasma apolipoprotein electrophoresis showing absence of the apo A-I band.

**96.8.3.4 Treatment.** Apo A-I deficiency has no specific treatment; currently available drugs are minimally effective at raising HDL. A reasonable treatment strategy is to improve the plasma LDL:HDL ratio using LDL-lowering pharmacotherapy in combination with CVD risk factor reduction and prevention through lifestyle and diet.

## 96.9 DISORDERS WITH PRIMARILY ELEVATED TRIGLYCERIDES

### 96.9.1 Hyperchylomicronemia

**96.9.1.1 Clinical Features.** Hyperchylomicronemia seen in pediatric patients is predominantly due to one of two monogenic disorders affecting the peripheral metabolism of TG-rich, intestinally derived CM particles, namely, LPL deficiency and apo C-II deficiency.

Recurrent pancreatitis is relatively common and is thought to result from episodic pancreatic ischemia secondary to hyperchylomicronemia (132). Patients usually complain of mild to severe abdominal pain with nausea and vomiting. Other physical signs during childhood include failure to thrive, hepatosplenomegaly, lipemia retinalis and eruptive xanthomata over extensor surfaces and buttocks (46a). Presentations during infancy can be heterogeneous and may include other signs such as intestinal bleeding, pallor, anemia, irritability, diarrhea, seizures and encephalopathy (133). Patients typically have extremely elevated fasting TG >10 mmol/L (134) (>900 mg/dL), although pancreatitis usually occurs when TG >20 mmol/L (>1800 mg/dL) (135). LDL and HDL levels are usually subnormal (136). Plasma is milky and turbid, or lipemic, because of the high TG content (134).

**96.9.1.2 Molecular Genetics.** Some patients with plasma TG >95th percentile have rare monogenic disorders resulting from homozygous LOF mutations in *LPL*, *APOC2*, *APOA5*, *LMF1* or *GPIHBP1* genes, respectively (136,137). Complete LPL deficiency is an extremely rare (~1:10<sup>6</sup>) AR disease resulting from homozygosity or compound heterozygosity for mutant LPL (138). More than 100 different dysfunctional *LPL* variants have been reported and almost all reduce or eliminate LPL activity in the homozygous state, preventing hydrolysis and resulting in accumulation of TG-rich lipoproteins (TRLs), primarily CMs (139).

Less frequently, homozygous mutations have been shown in other molecules that interact with LPL, resulting in a comparable clinical phenotype (138). For instance, ~10 homozygous mutations in *APOC2*, which encodes apo C-II, a key cofactor for LPL, have been found in patients with familial chylomicronemia (138).

The physiological role of apo A-V was solidified by work in animal models (140). HTG is seen in some probands with homozygosity for rare LOF mutations in *APOA5* (141), although the phenotype is less severe clinically and biochemically than in patients with homozygous *LPL* or *APOC2* mutations. Apo A-V appears to play a focal role in hydrolysis of TRLs by enhancing LPL activity (142).

Another form of familial lipase deficiency and chylomicronemia results from homozygous mutations in *LMF1*, the human ortholog of the *cld* (combined lipase deficiency) gene in mice (137a). A few probands with chylomicronemia and pancreatitis have homozygous LOF mutations in *LMF1* (27). Studies in mice indicate that *Lmf1* is coexpressed in tissues that express *LpL* or *LipC*; its gene product localizes to the membrane of the endoplasmic reticulum, stimulating maturation of both lipases (27). Thus, human mutations in *LMF1* likely cripple transport of the target lipases.

In addition, some patients with hyperchylomicronemia have homozygous mutations in *GPIHBP1* (143), which encodes glycosylphosphatidylinositol-anchored HDL-binding protein 1. The mouse ortholog *Gpibp1*,

when deleted, also caused severe HTG (28). Recently, *GPIHBP1* was shown to be responsible for entry of LPL into the capillary lumen (144).

Finally, other rare monogenic conditions that do not primarily affect lipoprotein metabolism can result in severe HTG. These include the inherited syndromes of lipodystrophy (145), which have variable patterns of inheritance and a wide range of clinical features, such as variation in the distribution and loss of adipose tissue. Patients with severe inherited lipodystrophy can present with chylomicronemia and pancreatitis (145).

**96.9.1.3 Diagnosis.** Early diagnosis is important to prevent chronic pancreatitis and pancreatic necrosis (146), although often pancreatic function deteriorates very slowly (147). CVD risk may also be increased in these patients (132,148). An infant or child presenting with hyperchylomicronemia syndrome was tested for LPL deficiency by performing an LPL assay using postheparin plasma. Apo C-II deficiency can be diagnosed if reduced LPL activity from postheparin plasma normalized upon addition of exogenous apo C-II (149). However, presently, direct gene sequencing has become the more expedient diagnostic method for both disorders, and also for detecting even rarer homozygous mutations in *APOA5*, *LMF1* or *GPIHBP1*.

**96.9.1.4 Treatment.** Unfortunately, hyperchylomicronemia resulting from deficiency in LPL or apo C-II is challenging to treat with existing pharmacologic approaches. Although much rarer than even LPL or apo C-II deficiency, treating deficiencies in apo A-V, *LMF1* and *GPIHBP1* appears similarly challenging. Fibrates, niacin and fish oil are not particularly effective in improving the biochemical disturbances in these patients (132). The cornerstone of treatment is severe dietary fat restriction, although recommended targets vary from less than 50g/day, or <25% of the total daily caloric intake (132) to less than 20g/day, or under 15% (150). However, such a dietary regime is often very difficult for most patients to follow. Experimental adenoviral-mediated LPL gene therapy is under evaluation for documented LPL deficiency (151).

## 96.10 DISORDERS WITH MULTIPLE LIPOPROTEIN DISTURBANCES

### 96.10.1 Familial Combined Hyperlipidemia

**96.10.1.1 Clinical Features.** The familial combined hyperlipidemia (FCHL) (HLP type 2B) biochemical phenotype is seen in up to 1 in 40 adults and is characterized by elevated total and LDL cholesterol and TG (all >90th percentile for age and sex) in probands and affected relatives, and may be the most common genetical dyslipidemia causing CHD (152). Although defined clinically based on biochemical phenotypes, affected individuals in a few families appear to demonstrate

physical findings that are typical for other dyslipidemias, such as skin or tendinous xanthomas. CHD risk in FCHL is related to the degree of TG elevation (40).

**96.10.1.2 Molecular Genetics.** Of the linkage and association studies performed in FCHL families over the 1980s and 1990s, the most promising gene identified as contributing to susceptibility is *USF1*, an upstream transcription factor with multiple targets in metabolic pathways (153). Recent association studies seem to indicate that FCHL is not a monogenic disorder, but rather a complex trait that results from the accumulation of numerous small-effect common alleles together with a few large-effect rare mutations that are individually associated with elevated TG or LDL cholesterol levels and an important contribution from secondary environmental or nongenetic metabolic factors (154).

## 96.10.2 Hepatic Lipase (HL) Deficiency

**96.10.2.1 Clinical Features.** In HL deficiency, compound heterozygosity for mutant *LIPC* resulted in elevated plasma HDL and apo A-I, and also in increased concentrations of IDL, TG enrichment of LDL and HDL, abnormal catabolism of remnant lipoproteins, and failure to remodel HDL and early CHD (155). This is consistent with the concept that HL contributes to the degradation of TGs in CE-rich particles such as LDL and HDL.

**96.10.2.2 Molecular Genetics.** The deficiency of HL is very rare, with <5 reported kindreds who had affected individuals with homozygous mutations in the *LIPC* gene encoding HL (156).

**96.10.2.3 Diagnosis.** A molecular diagnosis can be made using DNA sequencing. A biochemical diagnosis of HL deficiency can be derived from total lipolytic activity measured in plasma after intravenous injection of heparin.

**96.10.2.4 Treatment.** There is no specific treatment for the elevated levels of compositionally abnormal HDL in HL deficiency. When CVD risk is increased, the abnormal lipoprotein profile can be managed with a diet reduced in total calories and fat content, and a statin plus or minus a fibrate to correct the predominant abnormality of non-HDL lipoprotein fractions. Reduction in CVD risk in general terms—management of blood pressure, diabetes, and obesity, with smoking cessation—should be evaluated on a case-by-case basis.

## 96.10.3 Dysbetalipoproteinemia

**96.10.3.1 Clinical Features.** Remnant lipoproteins, known collectively as  $\beta$ -VLDL and including IDL, have density <1.006 g/ml and migrate in the beta-position on agarose gel electrophoresis (157). Some VLDL remnants are considered to be IDL. The archetypal disorder of IDL excess is called dysbetalipoproteinemia (DBL) or HLP type 3. Remnant lipoproteins are normally rapidly catabolized by apo E-mediated RME to

LDLR, the cell-surface heparan sulfate proteoglycans/LDLR-related protein complex, or heparan sulfate proteoglycans alone. The dyslipidemia in these patients, a combined elevation of total cholesterol and TG, usually becomes manifest in the third decade of life. CVD in these patients involves both multiple vascular beds (158).

**96.10.3.2 Molecular Genetics.** The prevalence of DBL is ~1:10,000 (158). Disease expression requires homozygosity for the *APOE* E2 isoform, which differs from the common E3 isoform by a single amino acid substitution (R158C). Because ~1% of Caucasians are E2/E2 homozygotes, secondary environmental, metabolic or genetic factors are required for disease expression. Recently, part of the genetic component of DBL was shown to be the accumulation of numerous small-effect common alleles and a few large-effect rare mutations that are individually associated with higher TG levels (159). Other rare *APOE* mutations cause this phenotype, and are associated with AD inheritance and variable clinical severity (158).

**96.10.3.3 Diagnosis.** Patients with DBL typically have elevations of cholesterol and TG to about equal concentrations (~7.5 mmol/L or ~300 mg/dL), an elevated ratio of CE to TG in VLDL, characteristic skin findings (tuberous and/or palmar xanthomas) and early atherosclerosis.

**96.10.3.4 Treatment.** The dyslipidemia can be managed with a diet reduced in total calories and fat content, and either a statin or a fibrate to correct the predominant abnormality of non-HDL lipoprotein fractions. Reduction in CVD risk in general terms—management of blood pressure, diabetes, and obesity, with smoking cessation—should be determined on a case-by-case basis.

## 96.10.4 Familial Combined Hypolipidemia

**96.10.4.1 Clinical Features.** A single four-generation family had affected individuals with very low LDL cholesterol, HDL cholesterol and TG, but none of the systemic clinical features of ABL or HHBL, and no clear evidence of resistance to atherosclerosis or of hepatic steatosis. Only one family with this condition has so far been reported (160).

**96.10.4.2 Molecular Genetics.** Whole-genome exome sequencing found that affected subjects were compound heterozygotes for two nonsense variants in *ANGPTL3*, namely, S17X and E129X (160). Relatives heterozygous for either mutation had plasma levels of LDL cholesterol and TG that were intermediate between the levels in persons with neither or both mutations, consistent with a codominant mode of inheritance. In contrast, the level of HDL cholesterol segregated as a recessive trait: relatives who carried both nonsense alleles had significantly lower plasma HDL cholesterol levels than those with one or no mutations.

**96.10.4.3 Treatment.** Given that the primary phenotype was biochemical without obvious clinical sequelae, no specific treatment is indicated for the condition.

## 96.11 OTHER DYSLIPOPROTEINEMIAS

### 96.11.1 Sitosterolemia

**96.11.1.1 Clinical Features.** Sitosterolemia, also known as phytosterolemia, is usually detected in pediatric patients. The defect produces a selective increase in plasma concentrations of plant sterols or phytosterols, including sitosterol and campesterol, which are present at concentrations of 100 and 10 times higher than normal, respectively (161). Plant sterols consumed by humans are not utilized, and their absorption from the intestine is selectively impeded: <5% of dietary plant sterols are absorbed compared to ~50% of dietary cholesterol. Patients with sitosterolemia accumulate plant sterols in many tissues, but have some features in common with HoFH patients, such as elevated plasma cholesterol, xanthomata, and early CVD due to atherosclerosis of the ascending aorta and coronary ostia (161). However, sitosterolemia is distinguished from HoFH by the absence of corneal arcus and by several additional key symptoms including recurrent joint arthritis, splenomegaly, hemolysis and platelet abnormalities (161). The total plasma cholesterol range is elevated, but is usually <10 mmol/L or 390 mg/dL (162).

**96.11.1.2 Molecular Genetics.** This condition results from mutations in the *ABCG5* and *ABCG8* genes (10), which together encode a heterodimeric G5/G8 protein. In normal individuals, the G5/G8 transporter in enterocytes rapidly returns most absorbed phytosterols back to the intestinal lumen before they can reach the systemic circulation. Phytosterols that do enter the circulation are then probably secreted into the bile by hepatocytes using the liver G5/G8 transporter (163). *ABCG5* and *ABCG8* mutations causing dysfunctional G5/G8 transporters result in severely increased plasma phytosterol concentrations; these sterols are incorporated into cholesterol-carrying lipoproteins.

**96.11.1.3 Treatment.** Treatment involves dietary elimination of all sources of noncholesterol sterols, including common foods such as vegetable oils, margarine, nuts, olives, avocados and shellfish (161). BAS and ezetimibe lower both plasma cholesterol and plant sterol levels, while statins produce minimal response because of their selective reduction in plasma cholesterol, each ultimately via hepatic LDLR upregulation (164).

### 96.11.2 Lysosomal Acid Lipase (LAL) Deficiency

**96.11.2.1 Clinical Features.** Wolman disease and cholesteryl ester storage disease (CESD) are characterized, respectively, by the production of nonfunctional and

partially functional LAL (165). CESD is a disease of adolescence and adulthood, while Wolman disease is a neonatal disease often leading to death during the first year of life (166). CESD typically presents with hypercholesterolemia and hepatomegaly that can progress to hepatic fibrosis (166). Wolman disease has a more dramatic presentation during infancy, with clinical features that include hepatosplenomegaly, failure to thrive, steatorrhea, anemia, jaundice and an acutely ill appearance (166,167). Pathological examination shows TG and cholesterol accumulation in liver, spleen, intestinal lining, bone marrow and vasculature, as well as severe adrenal calcification (166,167). Plasma cholesterol and TG levels are not necessarily dramatically elevated in Wolman disease (166).

**96.11.2.2 Molecular Genetics.** LAL is the enzyme responsible for intracellular hydrolysis of TG and CE by many tissues (168). Homozygous or compound heterozygous mutations in the *LIPA* gene encoding LAL underlie lipid storage diseases characterized by intracellular accumulation of unhydrolyzed lipids (168).

**96.11.2.3 Treatment.** While patients with CESD can have increased LDL cholesterol that responds to treatment with statins and ezetimibe (169), there is no specific treatment for Wolman disease. The prognosis for Wolman disease is often unfavorable, although some remarkable results have been obtained showing the feasibility of bone marrow transplantation, enzyme therapy and gene therapy (170). One report showed promise for early umbilical stem cell transplantation as a curative intervention (171).

### 96.11.3 Elevated Lipoprotein(a)

The biochemical and functional complexities of lipoprotein(a) (Lp(a)) have made it hard to understand its role in atherosclerosis (172). Lp(a) comprises LDL with a single molecule of apo B-100 linked to the polymorphic protein apo(a). The structural similarity between apo(a) and plasminogen, together with the LDL moiety suggest a prothrombotic or atherogenic role, or both. Older retrospective case-control studies and more recent population-based prospective genetic epidemiological studies (173) suggest a strong association between Lp(a) concentration and CHD risk. While there are no reported monogenic syndromes of Lp(a) excess, size polymorphism of the *LPA* gene on chromosome 6q26–27 is responsible for much of the interindividual variation in plasma Lp(a) concentration (174).

**96.11.3.1 Treatment.** If elevated Lp(a) is a concern, the focus should be on general CVD risk reduction, including LDL cholesterol reduction with a statin. In addition, niacin-based preparations reduce plasma Lp(a) levels, although there is no randomized clinical trial evidence that reduction to a specific target level reduces CVD end points.

### 96.11.4 Common Polygenic Dyslipidemia

In contrast to rare monogenic syndromes, most adult patients with dyslipidemia do not have a single genetic determinant that fully explains their clinical phenotype (3). While lipid abnormalities tend to be found at higher prevalence in relatives of these patients, there is no clear-cut pattern of inheritance and specific components of the lipoprotein profile may differ in affected relatives.

Recent genome-wide association studies (GWAS) have identified numerous genetic loci associated with plasma lipid levels (175). Some of the genes with common variants that have small effects on complex traits were already known to be important in lipoprotein metabolism, for instance, because they harbor rare large-effect variants in monogenic disorders. Therefore, previously unknown or unappreciated genes identified using this approach may prove to have some role in lipoprotein metabolism.

The role of multiple small-effect genetic variants as determinants of complex lipid and lipoprotein phenotypes was seen in a study of common complex HTG (176). For instance, in “garden variety” HTG, in both individual patients and across cohorts of patients with dyslipidemia, there was an accumulation of small-effect common variants from GWAS (154). Risk alleles for each of these common variants can be tallied to provide propensity or susceptibility scores for individuals. In addition, patients with common HTG are much more likely to have heterozygous rare variants in genes that contain common small-effect variants from GWAS studies (154). These increase the risk of expression but are not an absolute guarantee of developing HTG; the presence of secondary nongenetic or environmental factors

is still required. The clinical value of genetic risk scores for common nonmonogenic dyslipidemia is not yet clear; these may be useful for prognostication or perhaps personalized therapeutic approaches (176).

### 96.11.5 Secondary Dyslipidemias

Common dyslipidemias are often associated with other conditions, such as type 2 diabetes, obesity, alcoholism, hypothyroidism, pregnancy, renal failure, or drug use, and hence are termed secondary. Secondary dyslipidemias often have a strong genetic component, since some exacerbating conditions are frequently but not universally associated, suggesting that subjects who develop secondary dyslipidemia might have a subtle inherited metabolic defect that confers susceptibility. For example, abdominal obesity, metabolic syndrome (Table 96-12) 180 and type 2 diabetes have important effects on lipoprotein metabolism, and both these traits are highly heritable. It is important to distinguish between primary and secondary dyslipidemias, since this may determine the preferred means of intervention. Table 96-13 lists some conditions associated with secondary dyslipidemias.

## 96.12 GENERAL PRINCIPLES IN THE MANAGEMENT OF DYSLIPIDEMIA

CVD in the presence of mild-to-moderate polygenic dyslipidemia is common on a population-wide basis, while the monogenic disorders are relatively rare as a group. Several national guidelines provide advice for appropriate screening (Table 96-14) and management of dyslipidemia in the adult general population that does not specifically apply to the severe monogenic or

familial forms of dyslipidemia discussed earlier. The foundation of management for all patients is diet and lifestyle modification (Table 96-15). After a patient has survived a CVD event, or has clinical signs of atherosclerosis, or is asymptomatic but living with a high

Stress management

level of risk due to a high burden of risk factors such as smoking, diabetes, hypertension, obesity and family history, lipid-lowering therapy, specifically statins to reduce LDL cholesterol, can reduce the risk of future CVD events, even when baseline lipid levels are relatively normal.

Numerous national agencies such as the United States' National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) III (Table 96-7) and the Canadian Cardiovascular Society (Table 96-8) recommend LDL cholesterol as the primary target of therapy to reduce CVD risk. LDL cholesterol goals are recommended for patients stratified into particular risk categories, as determined using risk algorithms such as the Framingham risk score or the Reynolds risk score 126. For instance, subjects with

CHD or a CHD risk equivalent should aim for optimal LDL cholesterol  $<2.0$  mmol/L (or 78 mg/dL) according to Canadian guidelines or  $<1.8$  mmol/L (or 70 mg/dL) according to the updated NCEP ATP III<sup>56</sup> (Tables 96-8 and 96-7, respectively). Treatment of patients at lesser CHD risk proceeds in a graded manner. Intervention to reduce LDL cholesterol includes lifestyle management and, if necessary, pharmacologic therapies.

However, as noted earlier, certain monogenic disorders are associated with dramatically increased CVD risk, placing these individuals into the highest risk strata. These individuals will almost always require comprehensive and assertive management of lifestyle factors, with specific pharmacologic therapies as required for the individual conditions.

### 96.12.1 Dietary Intervention

Dietary interventions include (1) overall reduction in intake and reduced portion sizes, (2) redistribution of relative quantities of sources of calories (e.g. replace “high glycemic index” foods with complex carbohydrates, replace trans and saturated fats with monounsaturated and polyunsaturated fats), (3) addition or enhancement of specific foods that may have functional effects on the lipid profile (e.g. add soluble fiber or plant sterols), and (4) elimination of specific components that perturb the lipid profile (e.g. eliminate alcohol in some patients with elevated TG).

The NCEP ATP III advises that carbohydrate and protein intake should be 55–60% and 15–20%, respectively, whereas total and saturated fat should be  $<25$ –35% and  $<7$ %, respectively, of total calories, with restrictions on dietary cholesterol ( $<200$  mg/day), saturated fat ( $<7$ % of total calories/day), polyunsaturated fat (up to 10% of total calories), monounsaturated fat (up to 20% of total calories) and increased intake of fiber (20–30 g/day, of which half should be soluble fiber). The intake of animal products should be reduced. In obese patients, weight correction through reduction in total caloric intake is mandatory and may normalize the lipid profile. In normal-weight patients an isocaloric replacement of fat with carbohydrates is often effective. Plant sterols and stanols at intakes of 2–3 g daily can lower LDL cholesterol by 6–14%. Alcohol raises plasma TG, especially in people with an underlying predisposition, although it can also raise plasma HDL cholesterol; it is recommended to limit alcohol intake in individuals with moderate to severe dyslipidemia.

In general, the severity of the dyslipidemia dictates the intensity of the intervention. For less severe dyslipidemia, restricting saturated fat while increasing aerobic activity may substantially improve lipid levels. For severe hyperchylomicronemia, recommended fat intake is restricted further to 10–15% of total calories, with reductions in both saturated and unsaturated fat. In an adult, this represents 15–20 g/day of fat. A specialized dietician can be very helpful in these circumstances.

### 96.12.2 Physical Activity

Regular exercise is important in recalibrating the balance between caloric intake and expenditure, thus contributing to weight loss. Exercise also lowers blood pressure and improves insulin resistance; more directly it reduces plasma cholesterol and TG, and raises HDL cholesterol levels. This increases the catabolism of TRLs and tissue lipolysis. Recommendations relating to the intensity of regular exercise depend on the health and fitness of the patient; adults and children need to engage in activities equivalent to a daily total of 30–60 min of moderately intense physical activity three to five times per week.

### 96.12.3 Pharmacological Therapy

In general, drug therapy may be started together with lifestyle interventions in high-risk patients. The patient’s level of risk guides the timing of treatment initiation and also the intensity of the treatment. Moderate- or low-risk patients may be started on medication after a trial period of lifestyle interventions (Table 96-7). The main priority of drug therapy is to achieve the LDL cholesterol target level. Therefore, once drug therapy has been decided upon for a general patient with high CVD risk and mild-to-moderate complex dyslipidemia, an LDL-lowering drug is almost always the first step.

The response to drug therapy should be checked in about 6–8 weeks. If the LDL cholesterol target is not achieved, options include upward titration, switching to a more potent member of the same drug class or addition of a second-line agent. If the patient develops a drug-related adverse event, alternatives include a trial period off the medication to confirm a temporal relationship, empirically switching with the same class in the event that the side effect is agent specific rather than class specific, or switching to a second-line drug, such as a BAS, cholesterol absorption inhibitor, niacin-based therapy or fibrate. In HeFH or FCHL, combination regimens, such as statin plus a BAS, niacin, fibrate or cholesterol absorption inhibitor, are often required to attain target levels.

**96.12.3.1 HMG-CoA Reductase Inhibitors.** HMG-CoA reductase inhibitors (statins) block the rate-limiting step in de novo cholesterol biosynthesis, which depletes intracellular cholesterol and upregulates the LDLR, increasing LDL catabolism and lowering LDL cholesterol levels. Statins also appear to have a minor effect on reducing secretion of apo B-containing lipoproteins. The evidence that CVD end points and mortality are reduced by statins is overwhelming. Considering their very widespread use in cardioprotection, statins are generally well tolerated and only rarely cause myopathy or hepatic toxicity. Their place as front-line drug therapy in patients with mild-to-moderate dyslipidemia is incontrovertible. Available statins include lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin and pitavastatin (Table 96-16).

**TABLE 96-16 Dosing and Efficacy of Currently Available Drugs for the Treatment of Dyslipidemia**

Drug	Class	Mechanism	Dosing	Approximate LDL Cholesterol Reduction (%)
Atorvastatin	Statin	HMG-CoA inhibition	10–80 mg/day	35–50
Fluvastatin	Statin	HMG-CoA inhibition	20–80 mg/day	24–38
Lovastatin	Statin	HMG-CoA inhibition	20–80 mg/day	26–38
Pitavastatin	Statin	HMG-CoA inhibition	1–4 mg/day	22–39
Pravastatin	Statin	HMG-CoA inhibition	10–40 mg/day	25–40
Rosuvastatin	Statin	HMG-CoA inhibition	20–80 mg/day	37–52
Simvastatin	Statin	HMG-CoA inhibition	5–80 mg/day	32–46
Fenofibrate	Fibrate	PPAR- $\alpha$ agonist	48 and 145 mg/day	–10 to 11
Gemfibrozil	Fibrate	PPAR- $\alpha$ agonist	600 mg twice daily	–6 to 11
Cholestyramine	BAS	Interrupts enterohepatic circulation	4–8 g one to two times daily	8–20
Colesevelam	BAS	Interrupts enterohepatic circulation	625 mg two to three times daily	7–18
Ezetimibe	Cholesterol absorption inhibitor	Blocks NPC1L1 transporter at intestinal brush border	10 mg/day	15–24

**96.12.3.2 Bile Acid Sequestrants.** BAS, such as cholestyramine, cholestipol, and colesevelam, are basic anion-exchange resins that bind BA in the intestine, interrupting the enterohepatic BA recirculation, diverting hepatic cholesterol into BA synthesis, and depleting intrahepatic cholesterol. The upregulation of LDLR increases LDL catabolism and decreases LDL cholesterol levels. BAS have a complementary mechanism of action and are additive to the LDL-lowering effects of statins. Despite evidence for reduction in CVD and CHD end points and their long track record of safety, BAS suffer from low compliance because of adverse gastrointestinal effects. Because BAS tend to raise serum TG, they should be avoided in persons with high TG ( $>400$  mg/dL or  $>5$  mmol/L). They are considered second-line agents to be added to maximally tolerated statin doses when LDL cholesterol targets are not reached. They can also be considered in persons who develop statin-related adverse effects.

**96.12.3.3 Cholesterol Absorption Inhibition.** Cholesterol absorption inhibitors work preferentially at the level of the luminal brush border of enterocytes in the upper intestine, reducing cholesterol content of CMs while maintaining the absorption of lipid-soluble vitamins or steroid hormones. Ezetimibe is thought to lower plasma LDL cholesterol by upregulating the activity of hepatic LDLR. Ezetimibe is available at a single dose of 10 mg daily and lowers LDL cholesterol levels by 18–25%, with no effect on other components of the lipid profile. The combination of a statin and ezetimibe can lower LDL cholesterol by ~70%. Compared to BAS and niacin, ezetimibe is well tolerated with minimal side effects. At this time, ezetimibe should still be considered as a second-line drug added to statin therapy when LDL cholesterol targets have not been reached or when statins cannot be tolerated as first-line therapy.

**96.12.3.4 Nicotinic Acid.** Nicotinic acid, or niacin, is a second-line agent for CVD risk reduction in patients with mild-to-moderate common dyslipidemia. It is also an

add-on therapy in higher risk persons who are not at LDL cholesterol target on highest tolerated statin dose and who have a low HDL cholesterol component to their risk profile. Niacin has multiple favorable effects on the lipid profile: doses of up to 2 g daily for extended release preparations or up to 3 g daily of the crystalline form can lower plasma TG by up to 45%, raise plasma HDL cholesterol by up to 25%, and reduce plasma LDL cholesterol by up to 20%. After almost six decades of clinical use, niacin's mechanism of action remains poorly understood, but it may, at least in part, reduce hepatic secretion of VLDL by inhibiting peripheral mobilization of FFA. Older clinical trials suggested a reduction in CVD events related to niacin treatment. However, niacin frequently causes light-headedness, cutaneous flushing and pruritus. These adverse effects can be minimized by initiating therapy at low doses and then gradually increasing the daily dose, along with the concomitant use of aspirin or by the use of extended-release niacin preparations. Other adverse effects include elevated liver enzymes, gastrointestinal upset, worsened glucose tolerance and elevated uric acid.

**96.12.3.5 Fibrates.** Fibrates, such as gemfibrozil, fenofibrate, bezafibrate and ciprofibrate (of which the latter two are not available in the United States) can reduce plasma TG by up to 50%, and can raise plasma HDL cholesterol by up to 20%, although these percentages vary between patients. The complex mechanism of action of fibrates includes modulation of the activity of peroxisome proliferator-activated receptor- $\alpha$ , PPAR- $\alpha$ , in the liver, resulting in the downregulation of the expression of apo C-III and upregulation of apo A-I, fatty acid oxidation, and LPL, thereby increasing fatty acid oxidation with reduction in VLDL production. Because the LDL lowering capacity is very modest and because large recent clinical trials show little to no benefit of fibrates added to statin therapy for CVD risk reduction in patients with normal to modestly increased TG levels (178), fibrate use

is mainly reserved for treatment of patients with severe HTG to reduce the risk of acute pancreatitis. Fibrates can also be considered as an add-on therapy for patients with high CHD risk who require consideration for a second agent because primarily TG remains elevated.

**96.12.3.6 N-3 (Omega) Fatty Acids.** Populations in countries where large quantities of fatty fish are consumed and whose diets are naturally high in alpha-linolenic acid and longer chain omega-3 FA appear to have a decreased CVD risk. N-3 ( $\omega$ 3) FA, such as eicosapentanoic and docosahexanoic acid, are components of both Mediterranean diet and fish oils. Omega-3 FA can reduce hepatic secretion of VLDL and thus reduce TG. Ingestion of 4 g/day of omega-3 FA, with caloric and saturated fat restriction, may reduce plasma TG by up to 20%. However, omega-3 FA are not effective in many patients when used as the sole TG-lowering therapy.

**96.12.3.7 Extracorporeal LDL Reduction in Homozygous Familial Hypercholesterolemia.** Untreated HoFH has been associated with premature mortality since patients have virtually no functional LDLRs to upregulate, so that medications such as statins have little to no effect. The mainstay of treatment in HoFH is one of several extracorporeal approaches to remove the accumulating LDL particles, such as weekly or biweekly serial plasma exchange, plasmapheresis or specific LDL apheresis using size exclusion columns or antibody-based affinity columns (179). These treatments have prolonged the atherosclerosis-free survival of HoFH patients, who now live long enough to have manifestation of unexpected CVD end points, specifically aortic root and valvular calcification, often requiring surgical replacement (73).

## 96.12.4 Emerging Therapies

**96.12.4.1 LDLR-Based Gene Therapy.** Trials of LDLR gene replacement in HoFH have shown variable improvements in the lipoprotein profile (180). Gene delivery systems that are currently under development include several virus-based approaches. To date, however, many inherent problems remain to be solved, and long-term success and efficacy must be further improved before these techniques pass the experimental stage.

**96.12.4.2 Microsomal Triglyceride Transfer Protein (MTP) Inhibition.** The cardioprotective biochemical phenotype in ABL due to mutations in MTP, i.e. extremely low levels of CMs, VLDL and LDL, inspired the development of an orally administered inhibitor of MTP, namely, lomitapide. Early-phase clinical trials in patients with severe elevations in LDL cholesterol, such as those with HoFH, showed that MTP inhibition significantly reduces plasma total and LDL cholesterol, and apo B (86). However, ~25% of patients in short-term studies developed transaminase elevations and accumulation of hepatic fat, although this became less severe with prolonged treatment.

**96.12.4.3 Interference with APOB Synthesis.** The cardioprotective biochemical phenotype in FHBL due to mutations in *APOB*, i.e. extremely low levels of VLDL and LDL, inspired the development of parenteral antisense RNA therapies. Antisense RNA therapy refers to agents that have a range of mechanisms that result in specific targeting and degradation of messenger RNA (mRNA). Instead of pharmacological targeting, these newer methods, including antisense oligonucleotides (ASOs) and ribonucleic acid (RNA) interference (RNAi), reduce translation by selectively degrading mRNAs. The first antisense RNA for the treatment of dyslipidemia is mipomersen, a 20-nucleotide ASO administered subcutaneously using nondaily or weekly dosing regimens. Mipomersen binds *APOB* mRNA sequence and targets the bound mRNA for degradation via the activation of endogenous RNase H enzymes. Mipomersen can reduce both apo B and LDL-C levels by up to 50% in HoFH (181). Common adverse effects include skin site reactions and, to a much lesser degree, fatty liver.

**96.12.4.4 Interference with PCSK9.** The cardioprotective biochemical phenotype and reduction in CVD events seen in individuals with mutations in *PCSK9*, i.e. extremely low levels of LDL cholesterol, inspired the development of drugs to target *PCSK9*. Both RNA interference and monoclonal antibody strategies are being developed.

**96.12.4.5 Cholesteryl Ester Transfer Protein (CETP) Inhibition.** The first CETP inhibitor, torcetrapib, increased HDL cholesterol markedly, but was associated with increased CVD event rates. While this raised concern that perhaps the mechanism itself was fundamentally flawed, further evaluation showed that torcetrapib had off-target effects, particularly an increase in systolic blood pressure and possible increase in serum aldosterone levels. Two newer members of the class, namely, dalcetrapib (182) and anacetrapib (183), affect neither blood pressure nor serum aldosterone. Because of their apparently superior safety profile, fairly comprehensive development and clinical trial programs are in progress for both these newer agents.

**96.12.4.6 Other Emerging Treatments.** Other pharmacological approaches that are under various stages of clinical development include the combination of extended-release niacin with the prostaglandin D2 inhibitor laropiprant, which reduces the incidence of niacin-induced flushing (184), and the thyroid receptor agonist eprotirome, which lowers total and LDL cholesterol and TG (185).

## 96.13 CONCLUSION

There has been considerable recent progress in understanding at least a portion of the molecular bases for severe monogenic dyslipidemias. Clear distinctions at the molecular and clinical levels are emerging between polygenic dyslipidemias that manifest during adulthood

and more severe dyslipidemias that present at younger ages. Monogenic disorders may be suspected in individuals who present with markedly deviated levels of plasma LDL-cholesterol, HDL-cholesterol or TGs or with the signs and symptoms of syndromes described in this review. Genetic analysis is becoming more practical and useful in the diagnosis and management of these patients. Since the molecular genetic bases for some extreme pediatric lipid disorders are being increasingly well understood, there is some hope for future treatments that take advantage of this understanding. Clinicians must determine the proximal, intermediate and long-term risk of complications and adjust their perspective and goals appropriate to the individual patient with dyslipidemia.

### Biography

**Rob Hegele, MD, FRCPC, FACP** is a Distinguished University Professor of Medicine and Biochemistry at the Schulich School of Medicine and Dentistry and holds the Jacob J Wolfe Distinguished Medical Research Chair in Human Genetics and the Martha Blackburn Chair in Cardiovascular Genetics at the University of Western Ontario. His laboratory studies the molecular genetic basis of lipid and metabolic disorders and has discovered the molecular genetic basis of 12 human diseases. He serves on national treatment guidelines committees for hypertension, diabetes, and dyslipidemia.

# CHAPTER 97

## Organic Acidemias and Disorders of Fatty Acid Oxidation

*Jerry Vockley*

University of Pittsburgh, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA, USA

This article is a revision of the previous edition article by Stephen I Goodman, volume 3, pp 2296–2309, © 2007, Elsevier Ltd.

### 97.1 ORGANIC ACIDEMIAS

Most organic acidemias are disorders of amino acid metabolism. They were first described in 1961 as a syndrome of mental retardation, hyperglycinemia and episodic ketoacidosis, neutropenia and thrombocytopenia induced by protein intake or infection. Ultimately, it was realized that this biochemical and clinical phenotype, which had become known as ketotic hyperglycinemia, was actually a manifestation of organic acidemias, and in particular, methylmalonic acidemia, propionic acidemia, and 2-methyl-3-hydroxybutyric acidemia.

Organic acidemias can present in many ways and the indications for organic acid screening are quite diverse. They include (i) features of ketotic hyperglycinemia (see previous discussion); (ii) an unusual body odor; (iii) acute disease in infancy, especially when associated with metabolic acidosis, hypoglycemia, or hyperammonemia; (iv) chronic or recurrent metabolic acidosis, with or without an anion gap; (v) static or progressive extrapyramidal movement disorder in childhood; (vi) Reye syndrome when recurrent, familial, or in infancy; (vii) the combination of ataxia, alopecia, and rash; and (viii) seizure disorder and/or developmental delay of unknown cause. Because most organic acids are effectively cleared from the bloodstream by the kidney, urine is the preferred fluid for analysis.

Diagnosis of these conditions depends on methods to separate and identify organic acids, and the most widely used of these is gas chromatography-mass spectrometry (GC-MS), in which organic acid derivatives are separated by gas chromatography and then passed into a mass spectrometer for identification. Tandem mass spectrometry (MS-MS) is a related technology in which compounds are separated by molecular weight by one mass spectrometer, fragmented as they exit, and identified on the basis

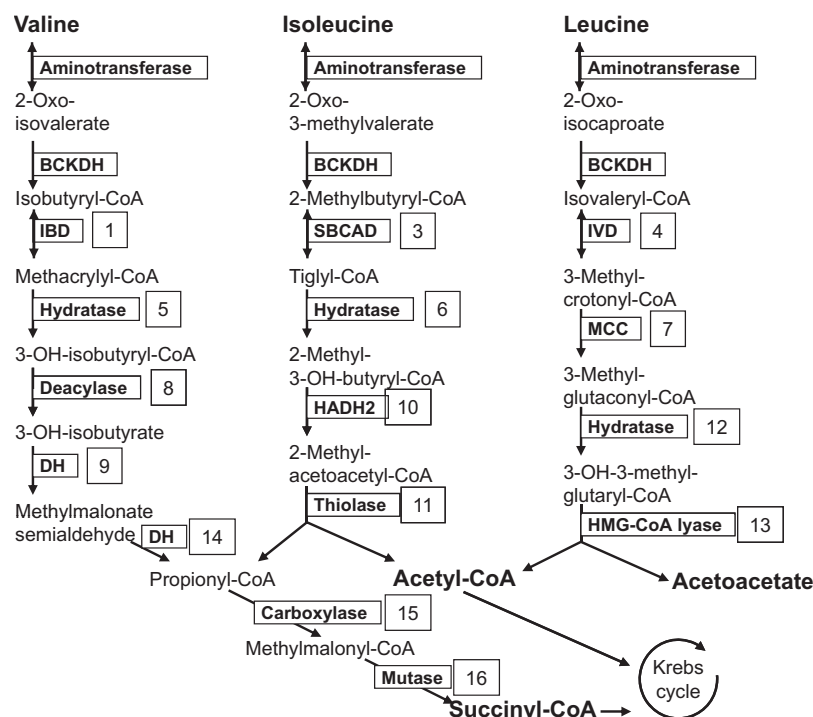

of their fragments by a second mass spectrometer. This technique is used to measure the acylcarnitine esters that accumulate in various fatty acid oxidations and organic acid disorders and serves the basis for effective newborn screening for many of these disorders. The convergence of many metabolic pathways especially onto the distal end of branched-chain amino acid catabolism has led to much confusion in diagnosis over the years. Diseases named for metabolites ultimately proved to be imprecise because of the accumulation of the same metabolites in more than one condition. Thus, it is best to discuss this group of disorders based on the enzymatic and/or molecular defect rather than metabolite accumulation.

Most described organic acidemias are inherited as autosomal recessive traits. Two are X-linked recessive. Prenatal diagnosis is typically accomplished through measurement of enzyme activity in cultured amniotic cells or a chorionic villus sample, or through measurement of diagnostic metabolites excreted by the affected fetus into the amniotic fluid. Molecular diagnosis is also possible when a proband's genetic defect has been identified.

#### 97.1.1 Branched-Chain Organic Acidemias

The largest group of organic acidemias derives from defects in the mitochondrial-based degradation of the branched-chain amino acids leucine, isoleucine and valine (Figure 97-1). The branched-chain amino acids enter mitochondria via a combined, reversible deamination and transport step performed by the vitamin B6-dependent branched-chain amino acid aminotransferases. Subsequently, the branched-chain ketoacids undergo oxidative decarboxylation by a single branched-chain ketoacid dehydrogenase active with all three substrates, another reversible reaction. Deficiency of this

**FIGURE 97-1** Pathways of branched-chain amino acid catabolism. The first two steps in the metabolism of branched-chain amino acids are reversible and their deficiency leads to amino acid rather than organic acid accumulation. BCKDH, branched-chain ketoacid dehydrogenase. Documented steps shown to cause disease in humans are numbered. 1, IBD, isobutyryl-CoA dehydrogenase; 2–4, isobutyryl, short branched-chain, and isovaleryl-CoA dehydrogenase; 5 and 6, methacrylyl-CoA and tiglyl-CoA hydratase, respectively; 7, MCC, methylcrotonyl-CoA carboxylase; 8, 3-hydroxyisobutyryl-CoA deacylase; 9, 3-hydroxyisobutyrate dehydrogenase; 10, 2-methyl-3-hydroxybutyryl-CoA dehydrogenase; 11, mitochondrial acetoacetyl-CoA thiolase; 12, 3-methylglutaconyl-CoA hydratase; 13, 3-hydroxy, 3-methylglutaryl-CoA lyase; 14, methylmalonate semialdehyde dehydrogenase; 15, propionyl-CoA carboxylase; 16, methylmalonyl-CoA mutase.

dehydrogenase leads to maple syrup urine disease and is discussed elsewhere in the book (Chapter 92). The remaining steps of the pathway are unique to the metabolites of each of the amino acids.

#### 97.1.1.1 Isovaleryl-CoA Dehydrogenase Deficiency.

Isovaleric acidemia (IVA) was the first condition to be recognized as an organic acidemia when the odor of sweaty feet that surrounded an infant with episodic encephalopathy was shown to be due to isovaleric acid (1,2). The disorder in leucine degradation is due to deficiency of isovaleryl-CoA dehydrogenase, the mitochondrial enzyme that oxidizes the first irreversible step in this pathway, isovaleryl-CoA to 3-methylcrotonyl-CoA (3).

**97.1.1.1.1 Clinical Course.** Early literature on IVA, an autosomal recessive disorder, emphasized two apparent phenotypes (4). The first was an acute, neonatal presentation with patients becoming symptomatic within the first two weeks of life (1,5–9). Patients appeared initially well, then developed vomiting and lethargy, progressing to coma. The second group presented with relatively nonspecific failure to thrive and/or developmental delay (chronic intermittent presentation) (5,6,10–12). Patients who survived an early acute presentation subsequently were indistinguishable from those with the chronic phenotype, and both groups of patients were prone to intermittent acute episodes of decompensation with minor illnesses (4). In reality, it is now apparent that patients can

fall anywhere on the spectrum of acute to chronic presentation and that there is probably little predictive value to the initial presentation. Moreover, with the application of MS-MS in newborn screening, potentially asymptomatic patients with one recurring IVD gene mutation and a mild biochemical phenotype are being identified in increasing numbers, representing an additional phenotype of IVA (13). This type may represent a biochemical phenotype only without the expression of any clinical symptoms (such as in benign hyperphenylalaninemia) and therefore needs to be differentiated from the classic forms of IVA.

**97.1.1.1.2 Diagnosis.** Diagnosis is most frequently made by newborn screening in countries where tandem MS-MS screening is performed. In symptomatic patients, the diagnosis is suggested by the clinical course and odor, and is confirmed by organic acid analysis or by demonstrating a deficiency of isovaleryl-CoA dehydrogenase in tissues. Odor may be mild or absent, however, and thus the clinical picture may be relatively nonspecific. The organic acids characteristic of the condition are isovalerylglycine and 3-hydroxyisovaleric acid; however, a long list of isovaleryl-CoA derived metabolites has been reported in blood and urine from patients with IVA and can assist in the confirmation of the disorder. Isovaleric acid itself, which is responsible for the odor, is not detected by most analytic methods. Most of the accumulated isovaleryl-CoA is excreted as the nontoxic glycine

and carnitine esters, but the amounts that accumulate during infection or after a protein load exceed the capacity of the liver to esterify it, and the carbon skeleton then appears in other compounds. The same clinical presentation and odor can be seen in glutaric acidemia type II, but urine organic acid analysis will effectively differentiate the two conditions.

**97.1.1.1.3 Treatment.** There are three goals for therapy of almost any organic acidemia, including IVA (3). The first is prevention of metabolic decompensation by careful clinical observation of the patient. During times of metabolic stress (including illness and fasting) endogenous substrate (leucine in IVA) from protein catabolism adds significantly to the production of metabolic intermediates. Achieving or maintaining anabolism is the main therapeutic approach to counter this problem. Reducing, but not eliminating, natural protein in the diet for 12–24 h may help in this regard, but only if additional other calories to promote anabolism can be given. The second goal is long-term reduction of the production of toxic metabolites from general catabolism through dietary manipulation. Total protein and caloric intake must be adequate to support normal growth in children and maintain an anabolic state, but this may require the use of an artificial protein source restricted to the appropriate amino acid for a portion of the protein requirement. The third goal of therapy is to prevent the accumulation of toxic metabolites by enhancing alternative metabolic pathways that produce alternative nontoxic compounds that are readily excreted. Carnitine is commonly used for this purpose in many of the organic acidemias. In IVA, glycine also effectively conjugates isovaleryl-CoA but is usually not needed to maintain homeostasis.

**97.1.1.1.4 Genetics.** IVA is inherited as an autosomal recessive trait. The gene encoding isovaleryl-CoA dehydrogenase has been cloned and localized to chromosome 15 (15q14–15), and multiple disease-causing mutations have been identified. Nearly half the mutant IVD alleles sequenced from infants diagnosed by newborn screening have been found to contain a common recurring missense mutation (932C>T; A282V) (13). Prenatal diagnosis can be achieved through enzyme measurement in cultured amniocytes, quantitation of isovalerylglycine in amniotic fluid, and molecular analysis when the mutations in the family are known.

## 97.1.2 3-Methylcrotonyl-CoA Carboxylase Deficiency

3-Methylcrotonyl-CoA carboxylase (3MCC) deficiency can be caused by a defect in the gene for this enzyme or as part of a multiple carboxylase deficiency (see later sections). Isolated deficiency, manifesting as isolated 3-methylcrotonylglycinemia was first described in 1970 in a female infant with feeding problems, developmental delay, severe hypotonia, and an odor like that of cat's

**FIGURE 97-2** Relation of carboxylation of 3-methylcrotonyl-CoA to the activities of biotinidase and HCS. HCS also links biotin to apocarboxylases for propionyl-CoA, acetyl-CoA and pyruvate, and biotinidase releases biotin from proteins and enzymes that contain it.

urine. The disorder is due to deficiency of 3-methylcrotonyl-CoA carboxylase, a biotin-containing enzyme that converts its substrate, an intermediate in leucine oxidation, to 3-methylglutaconyl-CoA (Figure 97-2).

**97.1.2.1 Clinical Course.** Early reports on patients with this condition reported episodes of vomiting, hypoglycemia, hepatomegaly, hyperammonemic encephalopathy, metabolic stroke, and hypotonia with developmental delay. Numerous affected babies have now been identified through newborn screening, most, if not all, of whom have remained well (14). Elevated metabolites characteristic of 3MCC deficiency have been identified through newborn screening in infants born to asymptomatic mothers with 3MCC deficiency (15). In conjunction with the identification of asymptomatic siblings of severely affected patients, the clinical relevance of the biochemical abnormalities related to this deficiency must be called into question.

**97.1.2.2 Diagnosis.** Diagnosis is usually made by organic acid analysis, and can be confirmed by enzyme assay in leukocytes or cultured fibroblasts. The most characteristic organic acids are 3-methylcrotonylglycine and 3-hydroxyisovaleric acid, and increased 3-hydroxyisovalerylcarnitine can be demonstrated by MS-MS. Serum carnitine may be low, possibly because of the excretion of 3-hydroxyisovalerylcarnitine. The characteristic but not specific metabolite identified through expanded newborn screening MS-MS is “C5-OH” carnitine. A similar organic aciduria is seen in biotin deficiency and combined carboxylase deficiency, but in these conditions together with 3-hydroxypropionic and methylcitric acids. The relationship of the metabolites to the clinical features of the disease is not well understood.

**97.1.2.3 Treatment.** Acute episodes of vomiting and hypoglycemia should be treated with fluids, glucose, and

electrolytes. The need for long-term restriction of protein or leucine is not established. Biotin supplementation (10–30 mg/day) has been reported but is of unproven effect. Carnitine supplementation may be warranted if serum levels are significantly reduced.

**97.1.2.4 Genetics.** 3-Methylcrotonyl-CoA carboxylase deficiency is transmitted as an autosomal recessive trait. The genes encoding the  $\alpha$ - and  $\beta$ -subunits are located on chromosomes 3 (3q25–27) and 5 (5q12–13), respectively, and disease-causing mutations have been identified in both (14). Prenatal diagnosis, although likely possible, has not been reported.

### 97.1.3 Multiple Carboxylase Deficiency (Biotinidase or Holocarboxylase Synthetase Deficiency)

Multiple carboxylase deficiency is caused by defects in the incorporation of the water-soluble B-complex vitamin biotin into or its release from four apocarboxylases acting on 3-methylcrotonyl-CoA, propionyl-CoA, acetyl-CoA, and pyruvate. Holocarboxylase synthetase (HCS) covalently binds biotin to the apocarboxylases, while biotinidase catalyzes its release from biotinyl- $\epsilon$ -lysine (biocytin) or biotin-containing peptides (Figure 97-2). Both these conditions are inherited as autosomal recessive traits, and frequently cause a syndrome of alopecia, skin rash, and encephalopathy.

**97.1.3.1 Clinical Course.** Biotinidase deficiency usually presents in infancy with a perioral dermatitis that resembles acrodermatitis enteropathica, patchy alopecia, and neurologic features such as ataxia, neurosensory defects, developmental delay, and convulsions, though later presentation with predominantly neurologic symptoms is possible (16). Biotinidase assay is now a part of many newborn screening programs and frequently identifies infants with partial deficiencies. These infants are likely to remain well, but late onset symptoms have been reported. HCS deficiency usually causes earlier and more severe disease, with ketoacidosis, alopecia, and a red and scaly total body eruption (17). Coma, apnea, and death often ensue if therapy is not begun promptly. In both conditions the rash may be complicated by superinfection with *Monilia*. There is sufficient overlap in time and severity of onset; however, accurate differentiation between the two can only be made by enzyme assay.

**97.1.3.2 Diagnosis.** Urine organic acid analysis shows increased 3-methylcrotonylglycine and 3-hydroxyisovaleric acid, together with methylcitric and 3-hydroxypropionic, and acylcarnitine analysis shows 3-hydroxyisovaleryl- and propionylcarnitine. HCS can be assayed in fibroblasts or leukocytes, and biotinidase can be assayed in serum. Dietary biotin deficiency, especially during parenteral hyperalimentation, can be biochemically indistinguishable from biotinidase deficiency (18).

**97.1.3.3 Treatment.** Large doses of biotin (10–30 mg/day) usually produce rapid clinical improvement and

almost complete disappearance of abnormal urine organic acids. The frequency of biotinidase deficiency, the ease with which it can be treated, and the irreversibility of the neurologic sequelae have led to its inclusion in several newborn screening programs, and many affected patients have now been detected and treated successfully before the onset of symptoms (16,19). The need for treatment of partial biotinidase deficiency remains controversial.

**97.1.3.4 Genetics.** Both conditions are transmitted as autosomal recessive traits. The genes that encode biotinidase and HCS have been localized to chromosomes 3 (3p25) and 21 (21q22.1), respectively. Numerous disease-causing mutations have been delineated in each gene (16,17,19,20). Both conditions can be diagnosed in utero by enzyme assay on cultured amniocytes or chorionic villus samples, and by mutation analysis, but prenatal diagnosis of an affected fetus has thus far been reported only in HCS deficiency (21).

### 97.1.4 3-Methylglutaconic Aciduria

Elevation of 3-methylglutaconic aciduria is seen in a heterogeneous group of disorders: 3-methylglutaconyl-CoA hydratase deficiency (Figure 97-1), Barth syndrome (cardiomyopathy due to tafazzin gene defects), mutations in the OPA3 gene (optic atrophy plus or Costoff syndrome), and cardiomyopathy with ataxia (due to mutations in the DNAJC19 gene) (Table 97-1) (22). Occasional patients with significant 3-methylglutaconic aciduria of unknown cause continue to be identified and are referred to as having the type 4 phenotype (23). While all these disorders share a similar biochemical phenotype, they are quite different disorders clinically.

**97.1.4.1 Clinical Course.** Patients with 3-methylglutaconyl-CoA hydratase deficiency have been reported to have a variable phenotype ranging from mild delay (including isolated speech delay) to more severe delay, cerebellar ataxia, and movement abnormalities and even quadriplegia. Older reports are likely to have confused hydratase deficiency with other causes of 3-methylglutaconic aciduria, but the variability persists even in newer reports with documented enzymatic or molecular diagnoses. Thus the full spectrum of this disorder remains to be determined. Barth syndrome is an X-linked disorder

**TABLE 97-1** Classification of Disorders Exhibiting Increased Excretion of 3-Methylglutaconic Acid

Type	Gene Defect
1	3-methylglutaconyl-CoA hydratase
2 (Barth syndrome)	Tafazzin
3	OPA3
4	Unknown
5	DNAJC19

characterized by cardiomyopathy, neutropenia and skeletal myopathy (24). Mitochondria are abnormal with tightly packed cristae and inclusion bodies. The cardiomyopathy may be congenital but can also be absent. In the latter setting, infections due to neutropenia suggest the diagnosis. In one report, the age distribution in 54 living patients was 0–49 years (24). Female carriers are usually healthy. Mutations in the tafazzin gene that encodes a mitochondrial cardiolipin transacylase are responsible for Barth syndrome (25). Secondary effects on the respiratory chain function and increased oxidative stress presumably lead to the pathophysiology in this disease. OPA3 deficiency presents with early-onset bilateral optic atrophy and late development of spasticity, extrapyramidal dysfunction and occasionally cognitive deficit (26). Cardiomyopathy and neutropenia are not present. An Iraqi-Jewish isolate has accounted for most reported cases. The function of the OPA3 gene is unknown, but it encodes at least two transcripts that are targeted to mitochondria (27). Mutations in DNAJC19 cause an autosomal recessive Barth-like syndrome (28). Described in 11 consanguineous Canadian Hutterite families, affected individuals had severe, early onset cardiomyopathy that tended to be progressive. They subsequently exhibited growth failure and cerebellar ataxia. Mild normochromic, microcytic anemia and hepatosteatosis may be present. DNAJC19 is a homolog of a yeast inner mitochondrial cochaperonin.

**97.1.4.2 Diagnosis.** 3-Methylglutaconic acid is identified in urine by standard GC-MS techniques. 3-Methylglutaric acid is also usually present. Levels are the highest in the hydratase deficiency and more modest in the other disorders. The hydratase activity can be measured in fibroblasts, but in practice molecular testing is probably easier clinically. Functional tests for the other disorders are not available, and so molecular testing is the only diagnostic option. In theory, prenatal diagnosis through metabolite analysis of amniotic fluid should be feasible,

but has not been reported yet. Molecular diagnosis can be applied prenatally.

**97.1.4.3 Treatment.** Unfortunately, therapeutic advances for 3-methylglutaconic acidemias have lagged far beyond the growing understanding of their molecular causes. Currently, no effective therapy exists for any of the recognized defects. Leucine restriction has not been shown to affect outcome.

**97.1.4.4 Genetics.** The genes for 3-methylglutaconyl-CoA hydratase, tafazzin, OPA3 and DNAJC19 are on chromosomes 9, X, 19, and 3, respectively. Mutations in all the genes related to disease have been identified. No ethnic predilection has been reported for hydratase or tafazzin deficiencies. OPA3 and DNAJC19 defects have been identified in Iraqi-Jews and Canadian Hutterites, respectively.

### 97.1.5 3-Hydroxy-3-Methylglutaryl-CoA Lyase Deficiency

Hydroxymethylglutaric acidemia is typically an early-onset disease. It is due to a deficiency of 3-hydroxy-3-methylglutaryl-CoA lyase, an enzyme involved in leucine oxidation and in ketone body biosynthesis (Figure 97-3). Identification by newborn screening with MS-MS offers the opportunity to intervene before symptoms appear.

**97.1.5.1 Clinical Course.** The condition most frequently presents in early infancy with hypoglycemia, metabolic acidosis, and hyperammonemia. In 30% of cases onset is between birth and day 5 of life or between 3 and 11 months of age and is frequently lethal (29). Older children present with episodic hypoketotic hypoglycemia, hepatomegaly, and encephalopathy after intercurrent infections. The latter form of the condition is frequently mistaken for Reye syndrome. Neurologic signs, mental retardation, and cerebral atrophy may follow if the condition is not recognized and treated. Rare first presentations in adulthood have been reported.

**FIGURE 97-3** Reaction catalyzed by hydroxymethylglutaryl-CoA lyase. (1) Methylglutaconyl-CoA hydratase. (2) Hydroxymethylglutaryl-CoA synthetase.

**97.1.5.2 Diagnosis.** This condition, and disorders of fatty acid oxidation, should be excluded in any infant or child with hypoketotic hypoglycemia. Organic acid analysis shows large increases in 3-hydroxy-3-methylglutaric, 3-methylglutaconic and 3-hydroxyisovaleric acids, especially after protein intake or in situations that favor the synthesis and utilization of ketone bodies. Note that the same pattern of metabolites is sometimes seen as a nonspecific marker of mitochondrial dysfunction and so follow up testing is mandatory. The diagnosis can be confirmed by demonstrating deficiency of hydroxymethylglutaryl-CoA lyase activity in leukocytes or cultured fibroblasts. Molecular testing is available. 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency can be identified by newborn screening with MS-MS, but the metabolite identified ("C5 hydroxycarnitine") is not specific, so urgent follow-up testing (urine organic acids) is required (30–32).

**97.1.5.3 Treatment.** Episodes of hypoketotic hypoglycemia should be treated with intravenous fluids, electrolytes, and glucose to reestablish an anabolic state. Long-term management is directed at avoiding fasting and the resulting hypoglycemia. Leucine restriction has been suggested but probably has limited effect (29). Carnitine supplementation may be helpful. The possible life-threatening consequences of acute attacks make it critical that parents bring the child to hospital as soon as possible whenever oral intake is reduced.

**97.1.5.4 Genetics.** Hydroxymethylglutaric acidemia is inherited as an autosomal recessive trait, and heterozygote detection is possible by demonstrating intermediate lyase activity in leukocytes. The gene encoding HMG-CoA lyase has been cloned and localized to chromosome 1 (1pter-p33) and multiple disease-causing mutations

have been identified (29,33). Prenatal diagnosis has been established by enzyme assay in cultured amniocytes, by metabolite analysis of maternal urine and amniotic fluid, and by mutation analysis on chorionic villus samples.

## 97.1.6 Short/Branched-Chain Acyl-CoA Dehydrogenase Deficiency

This enzyme was originally named 2-methyl branched-chain acyl-CoA dehydrogenase based on the substrate specificity of an enzyme purified from rat liver. At that time, it was not clear whether the same enzyme was active in both isoleucine and valine metabolism. Subsequently, cloning of the human genes showed the two pathways to use distinct enzymes and based on substrate specificity of the expressed human enzymes, the enzymes were designated short branched-chain- and isobutyryl-CoA dehydrogenase (SBCAD and IBD, for the isoleucine and valine enzymes, respectively) (Figure 97-4) (34). Deficiencies of both have now been described.

**97.1.6.1 Clinical Course.** SBCAD deficiency was first described in two patients with rather significant neurologic symptoms (35,36). However, it was soon noted to be present in high frequency in the Hmong population in the United States due to a common founder mutation (37). These individuals, largely identified through newborn screening and family studies, appear to be asymptomatic. Other studies on affected, non-Hmong individuals, again largely identified through newborn screening, corroborate the lack of symptoms (38). Currently, it seems appropriate to consider SBCAD deficiency a biochemical phenotype rather than a clinical disease, although long-term follow-up studies are necessary to

**FIGURE 97-4** Branched-chain acyl-CoA dehydrogenases. The third step in the pathway of all three branched-chain acyl-CoA dehydrogenases is mechanistically shared but performed by three distinct enzymes for each amino acid (3). A common amino transferase (1) and NAD-dependent dehydrogenase (2) generate branched-chain acyl-CoAs unique to each amino acid. Individual defects of the FAD-dependent branched-chain acyl-CoA dehydrogenases are known, and a secondary deficiency of all three is seen in multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type 2) because of inability to reoxidize  $\text{FADH}_2$ .

define any risks later in life. The major clinical concern is related to the characteristic metabolite (“C5 carnitine”) identified in babies by newborn screening with MS-MS. Identification of 2-methylbutyrylcarnitine and isovalerylcarnitine, isobaric 5 carbon species by MS-MS can be due to either SBCAD or IVD deficiency. Urine organic acid analysis can readily distinguish the two disorders.

**97.1.6.2 Diagnosis.** Most children will be identified through newborn screening with MS-MS. The characteristic metabolite (“C5 carnitine”) can be either 2-methylbutyrylcarnitine or isovalerylcarnitine since they are isobaric. Urine organic acid analysis can readily distinguish the two disorders and should be performed urgently because of the potential for a more severe phenotype due to IVA. Fibroblast or lymphocyte enzyme testing and molecular analysis are possible but of minimal clinical utility.

**97.1.6.3 Treatment.** No treatment is needed based on extensive experience with the Hmong population. In theory, there could be a risk for increased organic acidemia with intercurrent illnesses, so caution by parents at these times seems prudent, and they should seek medical attention if an affected child has protracted vomiting or dehydration.

**97.1.6.4 Genetics.** The SBCAD gene is located on chromosome 10q25–q26. A common c1165A>G mutation in the Hmong population leads both to protein inactivating amino acid substitution and exon skipping due to activation of a cryptic RNA splice site (37). Multiple other private mutations have been described (38).

### 97.1.7 2-Methyl-3-Hydroxybutyryl-CoA Dehydrogenase Deficiency

This enzyme in isoleucine metabolism has received several functional and genetic names since its discovery, which has led to some confusion in the literature. Based on one of the documented activities of the enzyme as a hydroxysteroid (17-beta) dehydrogenase, it has officially been assigned a gene symbol *HSD17B10*, replacing the *HADH2* designation more frequently seen in the inborn errors literature (Figure 97-1) (39). Two clinical phenotypes have been proposed to be the result of two different molecular mechanisms (40).

**97.1.7.1 Clinical Course.** The first patient identified with this deficiency, a male, exhibited a picture of progressive infantile neurodegeneration. He had unexplained metabolic acidosis with hypoglycemia in the newborn period. Modest psychomotor delay was reported in the first year of life, after which he developed choreoathetotic movements and neurointellectual deterioration (41). Metabolic acidosis has not been consistently seen in subsequent patients, but neurodegenerative symptoms have been uniform. Additional reported features in only a handful of patients include myoclonic or other seizures, hypotonia, optic atrophy, pigmentary or nonpigmentary retinopathy, sensorineural deafness, ataxia, dystonia, choreoathetosis, spastic

di-/tetraplegia, cardiomyopathy and mild dysmorphism (42). Cerebral magnetic resonance imaging (MRI) may be normal or exhibit characteristic findings including frontotemporal or frontoparietal atrophy, parieto-occipital periventricular white matter changes, and basal ganglia lesions. These patients have had severe or complete enzyme deficiency. Female patients are typically milder in keeping with X-linked inheritance, but severe disease can occur. X-linked mental retardation associated with choreoathetosis, and abnormal behavior in a four-generation pedigree has been linked to the *HSD17B10* gene but affected patients had near-normal enzyme activity, so an alternative mechanism of pathogenesis was postulated.

**97.1.7.2 Diagnosis.** Urine organic acids are notable for the accumulation of 2-methyl-3-hydroxybutyrate and tiglylglycine but not 2-methylacetoacetic acid. 2-Ethylhydracrylic and 3-hydroxyisobutyric acids have reported to be elevated. Enzyme and molecular testing are available. Prenatal testing has not been reported but should be possible.

**97.1.7.3 Therapy.** No specific therapies are available. Isoleucine restriction is probably not useful. Carnitine supplementation may provide nonspecific benefit related to organic acid conjugation.

**97.1.7.4 Genetics.** The *HSD17B10* gene is located at Xp11.2. Rare, private mutations inactivating enzyme activity have been reported in males with the full clinical picture (42). In the extended family with normal enzyme activity, a c.574C>A mutation in the codon for R192 does not alter the amino acid at this position but leads to an altered balance of RNA splicing products of unknown significance (40).

### 97.1.8 Mitochondrial Acetoacetyl-CoA Thiolase Deficiency

Mitochondrial acetoacetyl-CoA thiolase deficiency, also called  $\beta$ -ketothiolase, is a mixed disorder of isoleucine catabolism and ketone body production (Figure 97-5) (43). It presents with episodes of acidosis and encephalopathy most frequently occurring in conjunction with upper respiratory tract infections and other minor illness. Accumulation of 2-methyl-3-hydroxybutyric acid in urine is characteristic.

**97.1.8.1 Clinical Course.** The disease can present in the newborn period with hyperammonemia, metabolic acidosis, and severe ketosis, but more often presents beyond the first year of life with fasting or protein-induced episodes of vomiting, hepatomegaly, ketoacidosis, and encephalopathy (44). Mental retardation or death during an episode of ketoacidosis is common, but some patients are relatively free of symptoms. Intrafamilial variation has been reported (45).

**97.1.8.2 Diagnosis.** Organic acid analysis shows increased 2-methyl-3-hydroxybutyric acid, 2-methylacetoacetic acid, and tiglylglycine, but large amounts of normal

**FIGURE 97-5** Formation and metabolism of propionyl-CoA. (1) Acetoacetyl-CoA thiolase. (2) Propionyl-CoA carboxylase. (3) Methylmalonyl CoA racemase. (4) Methylmalonyl-CoA mutase. Adenosylcobalamin is the specific coenzyme for methylmalonyl-CoA mutase.

ketone bodies (3-hydroxybutyric and acetoacetic acids) will often obscure these increases when the patient is acutely ill. Indeed, it may only be possible to detect the diagnostic metabolites when the patient is free of symptoms, or after an oral load (100 mg/kg) of isoleucine. As in propionic and methylmalonic acidemia, glycine is frequently elevated in blood and urine. Enzyme assays to confirm the diagnosis, if necessary, can be performed on fibroblasts or lymphocytes. Mutation analysis is available, but genotype/phenotype correlations have been poor.

**97.1.8.3 Treatment.** Acute episodes should be treated with intravenous glucose and sodium bicarbonate. Long-term treatment with a low-protein diet, combined with the avoidance of fasting, decreases the frequency and severity of episodes of acidosis and permits normal growth and development if irreversible neurologic damage has not already occurred.

**97.1.8.4 Genetics.** The disease is inherited as an autosomal recessive trait. The mitochondrial acetoacetyl-CoA (*ACAT1*) gene is on chromosome 11, and multiple mutations in patients have been described (44). Prenatal diagnosis should be possible by enzyme assay in cultured amniocytes or chorionic villus samples, or by mutation analysis, but has not yet been reported.

### 97.1.9 Isobutyryl-CoA Dehydrogenase Deficiency

Of the three mitochondrial dehydrogenases involved in the third step of leucine, isoleucine, and valine metabolism, isobutyryl-CoA dehydrogenase (IBDH) in the valine pathway was the last to be definitively identified (Figure 97-2) (46). As with deficiency in its companion

enzymes in leucine and isoleucine catabolism, IBDH deficiency is largely identified through newborn screening by MS-MS. While an original symptomatic patient was described, those identified through newborn screening have been mostly well (47).

**97.1.9.1 Clinical Course.** The first patient with IBDH deficiency presented with carnitine and cardiomyopathy at 1 year of age (48). The child responded to carnitine supplementation and has no recurrence of cardiac disease or episodes of metabolic decompensation. Since the identification of the disorder, at least 15 additional patients have been reported, all identified through newborn screening (47,49,50). All but one have remained without symptoms. One patient had recurrent episodes of vomiting and dehydration with intercurrent illnesses (47). Of note, in keeping with observations in the original patient, this infant had significant decreases in plasma free carnitine (to  $<10 \mu\text{M}$ ) during these episodes, suggesting decreased muscle stores or excess renal loss of carnitine. She showed no signs of cardiomyopathy and had normal development at age 5 years.

**97.1.9.2 Diagnosis.** Isobutyrylcarnitine elevation in blood can be documented by tandem mass spectroscopy including newborn screening. Since MS-MS does not distinguish between butyryl- and isobutyryl carnitine, follow-up testing is necessary. Identification of isobutyrylglycine (as opposed to butyrylglycine) in urine differentiates the two disorders, and the diagnosis is then best confirmed by molecular analysis. Enzyme assay on fibroblasts or lymphocytes is possible but not readily available in many clinics.

**97.1.9.3 Treatment.** The need for treatment in IBDH deficiency is unproven. Carnitine losses in two patients

may indicate the need for carnitine supplementation at least when ill, but this remains conjecture. Valine restriction is not warranted.

**97.1.9.4 Genetics.** The gene for IBDH is the *ACAD8* gene located on chromosome 11q25. Multiple private mutations have been identified in patients (47).

### 97.1.10 3-Hydroxyisobutyryl-CoA Deacylase Deficiency

The next step in the valine catabolic pathway associated with a clinical disease is 3-hydroxyisobutyryl-CoA deacylase (Figure 97-1). (Methacrylyl-CoA hydratase deficiency has not been described.) Only two patients have been described with molecularly confirmed diagnoses (51,52). Accumulation of 3-hydroxybutyric acid in urine is not seen. Part of the pathology of this disorder is likely due to the highly reactive chemical nature of accumulated methacrylyl-CoA (51). Patients reported with 3-hydroxyisobutyric acid in urine likely have a different disorder.

**97.1.10.1 Clinical Course.** The first patient with 3-hydroxyisobutyryl-CoA deacylase deficiency presented with vertebral malformations and tetralogy of Fallot along with dysmorphic features (51). There was little growth or development and he died at age 3 months. Agenesis of the cingulate gyrus and corpus callosum was found on autopsy. Enzyme assay confirmed the diagnosis. The second patient appeared well at birth but exhibited neurodegeneration beginning at age 4 months. He had an episode of acute metabolic acidosis at age 14 months during which 3-hydroxyisobutyric acid was not identified in urine. MRI of the brain at that time demonstrated abnormalities in the globus pallidus and the midbrain, with asymmetrical involvement of the cerebral peduncles, although no structural abnormalities were noted. A number of patients have been reported with 3-hydroxyisobutyric acid in urine but no consistent clinical picture suggesting that they have a different disorder(s).

**97.1.10.2 Diagnosis.** 3-Hydroxyisobutyric acid does not accumulate in this disorder, probably because it is in equilibrium with methacrylyl-CoA, which is highly reactive. In the first patient, the alternative metabolites *S*-(2-carboxypropyl)cysteamine and *S*-(2-carboxypropyl)cysteine were seen. These compounds were not reported in the second patient but a hydroxy-C4-carnitine species was elevated. Since mass spectrometry cannot distinguish between hydroxybutyryl- and hydroxyisobutyrylcarnitine, this finding can also be consistent with a disorder of short-chain 3-hydroxyacyl-CoA deficiency. Both patients were shown to have enzymatic deficiency of 3-hydroxyisobutyryl-CoA deacylase on fibroblast assay, but the second patient also had partial deficiencies of respiratory chain complexes I and IV in muscle. Because of the complicated metabolite picture in these patients, it is likely that 3-hydroxybutyryl-CoA deacylase is underdiagnosed

and the full clinical spectrum remains to be described. Patients with 3-hydroxyisobutyric aciduria without deacylase deficiency also have had an inconsistent array of branched-chain organic acids in urine, again pointing to possible heterogeneity in diagnosis (53).

**97.1.10.3 Treatment.** No effective treatment has been reported for the deacylase defect. Experience with other distal disorders in the branched-chain amino acid degradative pathways suggests that valine supplementation is unlikely to be effective. Supplementation with cysteamine to increase conjugation of the accumulating methacrylyl-CoA is an attractive consideration but has not been tested. Carnitine supplementation may provide additional nonspecific conjugation of abnormal intermediates.

**97.1.10.4 Genetics.** The gene for 3-hydroxyisobutyryl-CoA deacylase is designated *HIBCH* and is located on chromosome 2q32.2. Mutation analysis has only been reported on one patient (52). Sequencing of the 3-hydroxyisobutyryl-CoA dehydrogenase gene in one patient with 3-hydroxyisobutyric aciduria failed to identify a mutation and thus the cause for this biochemical phenotype remains unclear (53).

### 97.1.11 Methylmalonate Semialdehyde Dehydrogenase Deficiency

Several reports in the literature describe patients with metabolite accumulation thought to be consistent with methylmalonate semialdehyde dehydrogenase deficiency but only one has subsequently been shown to have mutations in the gene for this enzyme (Figure 97-1) (54).

**97.1.11.1 Clinical Course.** The single patient with this disorder was identified on newborn screening for the unrelated finding of hypermethioninemia (54). Additional metabolic evaluation revealed high levels of urinary 3-hydroxyisobutyric acid and lesser elevations of 2-ethylhydracrylic acid, 3-aminoisobutyric acid, and  $\beta$ -alanine. Valine loading studies induced increased excretion of 3-hydroxyisobutyric acid in urine. A mutation in the *MMSDH* gene was ultimately identified (55). In the same study, three other patients previously suspected as having methylmalonate semialdehyde dehydrogenase deficiency were shown not to have *MMSDH* gene mutations, pointing to the lack of specificity of the metabolic findings. The patient was last reported at age 4 years to be well, so the clinical relevance of the biochemical phenotype is unknown.

**97.1.11.2 Diagnosis.** Based on the single bona fide patient, metabolite detection is unreliable. Patients with significant elevation of 3-hydroxyisobutyric acid in urine of otherwise unknown cause should have sequencing of the *MMSDH* gene.

**97.1.11.3 Treatment.** No treatment is warranted based on the single patient.

**97.1.11.4 Genetics.** The *MMSDH* gene is on chromosome 14q24.3. The single patient described was

homozygous for a single mutation, for which his parents were heterozygous, confirming recessive inheritance.

## 97.2 OTHER ORGANIC ACIDEMIAS

### 97.2.1 Ethylmalonic Encephalopathy

Deficiency of a mitochondrial sulfur dioxygenase leads to a characteristic phenotype known as ethylmalonic encephalopathy. Previously thought to be a disorder in branched-chain amino acid metabolism, the defect rather leads to the accumulation of sulfides within mitochondria, which in turn impairs mitochondrial energy metabolism.

**97.2.1.1 Clinical Course.** Ethylmalonic encephalopathy is characterized by neurodevelopmental delay and regression, prominent pyramidal and extrapyramidal signs, recurrent petechiae, orthostatic acrocyanosis, and chronic diarrhea (56,57). Pyramidal signs, hypotonia, microcephaly, failure to thrive, seizures, and episodic encephalopathy are common. Death usually occurs before age two; however, heterogeneity and longer survival has been reported (58,59). Symmetrical necrotic lesions in the deep gray matter structures are consistent neuropathological features of the disease. Most patients have been of Mediterranean origin. Ethylmalonic encephalopathy is caused by homozygous mutations in the *ETHE1* gene that encodes a mitochondrial sulfur dioxygenase (58). The resultant enzymatic deficiency leads to impaired catabolism of inorganic sulfur (sulfite), accumulation of H<sub>2</sub>S in tissues, and inhibition of the mitochondrial respiratory chain complex IV (60).

**97.2.1.2 Diagnosis.** Ethylmalonic acid accumulation in urine is the hallmark of ethylmalonic encephalopathy, but is nonspecific and can be intermittent in milder cases (58). The compound is likely the product of  $\alpha$ -carboxylation of butyrate elevated secondary to the inhibition of mitochondrial fatty acid oxidation. However, ethylmalonic aciduria is also seen in short-chain acyl-CoA dehydrogenase (SCAD) deficiency and primary respiratory chain deficiencies. Elevation of C4 and C5 carnitines in blood and isobutyrylglycine and 2-methylbutyrylglycine can also be seen in all these disorders. Urinary thiosulfate accumulation may be a more specific marker (60). Ultimately, in the correct clinical

setting, diagnosis by molecular testing should be pursued (61,62).

**97.2.1.3 Treatment.** Identification of the enzymatic cause of ethylmalonic encephalopathy has led to new therapeutic options in this previously untreatable disorder. In a single study, metronidazole, or N-acetylcysteine (a precursor of sulfide-buffering glutathione) substantially prolonged the lifespan of *ETH1*-deficient mice, with the combined treatment being additive. The same dual treatment caused marked clinical improvement in five affected children, with no reported adverse side effects (63). Additional studies will be needed to confirm the efficacy of this promising regimen.

**97.2.1.4 Genetics.** The molecular cause of ethylmalonic encephalopathy was first localized to chromosome 19q13 in a genetic mapping study and multiple mutations were ultimately identified in the *ETHE1* gene. All patients have mutations of both alleles, confirming autosomal recessive inheritance. No common mutations have been identified.

### 97.2.2 L-2-Hydroxyglutaric Acidemia

L- and D-2-Hydroxyglutaric acids are chiral enantiomers and require special separation techniques to be differentiated (64). Patients with L-2-hydroxyglutaric acidemia have a defect in the mitochondrial flavoenzyme L-2-hydroxyglutarate dehydrogenase that catalyzes the conversion of L-2-hydroxyglutarate to 2-ketoglutarate (Figure 97-6) (65). They exhibit a variable leukodystrophy. Of note, L-2-hydroxyglutarate does not seem to have a physiologic function in human metabolism (66). Rather it appears to be the product of mitochondrial L-malate dehydrogenase illicitly acting on 2-ketoglutarate. Thus, L-2-hydroxyglutarate dehydrogenase has been called a metabolic repair enzyme, preventing the accumulation of its extremely toxic substrate.

**97.2.2.1 Clinical Course.** The first patient described with this disorder had relatively nonspecific mental retardation (67). Additional patients were subsequently identified with mental retardation, cerebellar symptoms, and movement abnormalities with onset of symptoms in childhood (2). MRI revealed a consistent pattern including subcortical leukoencephalopathy, cerebellar atrophy, and signal changes in the putamina and dentate nuclei.

**FIGURE 97-6** Physiological role of L-2-Hydroxyglutarate metabolism. L-2-hydroxyglutarate dehydrogenase serves to oxidize its highly toxic substrate produced as a secondary reaction product of L-malate dehydrogenase in mitochondria.

Later onset patients have exhibited milder and relatively nonspecific symptoms including autism (68). Intriguingly, patients are at increased risk to develop CNS tumors, although the percentage so affected is still small (~5%) (69). Riboflavin (100 mg daily) and flavin adenine dinucleotide (FAD) (30 mg daily) supplementation have been reported to improve symptoms in separate patients (70,71). Successful pregnancy in an affected woman has been reported (72).

**97.2.2.2 Diagnosis.** 2-Hydroxyglutaric acid is identifiable in urine by routine organic acid analysis, but additional separation techniques are required to differentiate the L and D enantiomers (64). The metabolite is also elevated in brain. L-2-hydroxyglutaric acid is often elevated in glutaric academia type II, but other metabolites permit unequivocal differentiation of these disorders. Lysine is consistently elevated in blood and should not be confused with hyperlysinemia. Characteristic findings on MRI of the brain include a combination of predominantly subcortical cerebral white matter abnormalities and abnormalities of the dentate nucleus, globus pallidus, putamen, and caudate nucleus (73). Enzymatic assay is difficult and thus molecular analysis is probably the definitive diagnostic test of choice (74,75).

**97.2.2.3 Treatment.** Riboflavin (100 mg daily) and FAD (30 mg daily) supplementation have been reported to improve symptoms in separate patients but larger

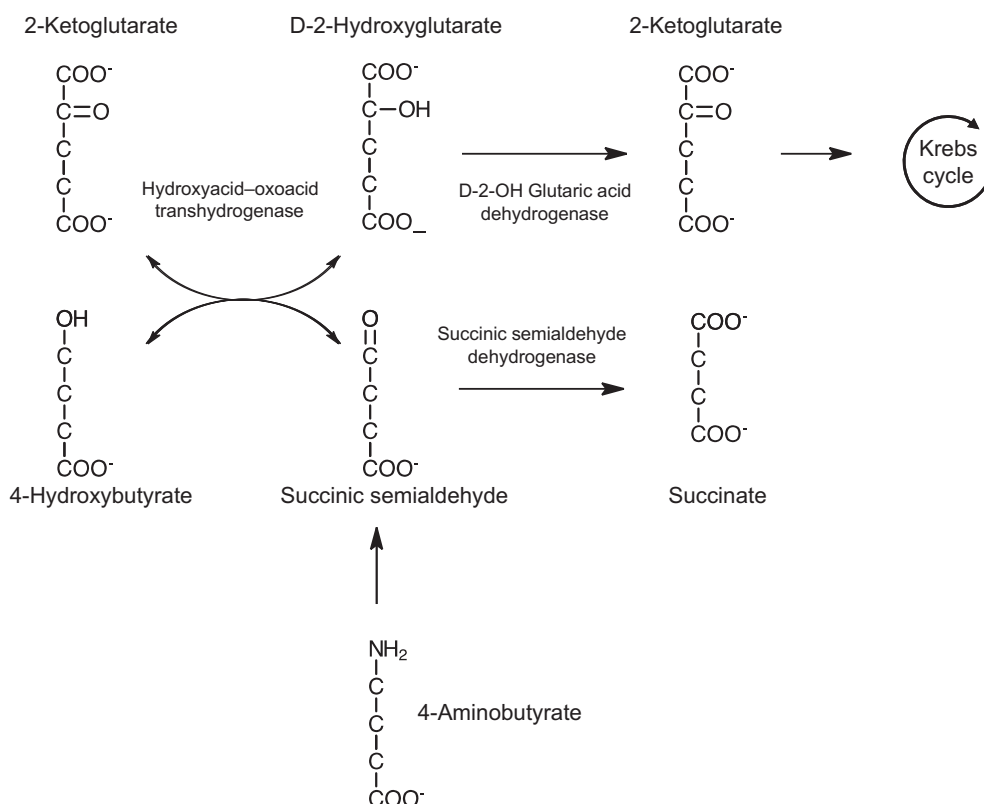

trials have not been performed (70,71). Carnitine may increase organic acid excretion nonspecifically.

**97.2.2.4 Genetics.** The L-2-hydroxyglutaric dehydrogenase (*L2GHDH*) gene is located on chromosome 14q22.1. Multiple private mutations have been reported. Turkish and Iraqi isolates exist (76,77).

### 97.2.3 D-2-Hydroxyglutaric Acidemia

D-2-Hydroxyglutaric acidemia is less frequent than its L-counterpart and has two genetic causes with variable symptoms. D-2-Hydroxyglutaric acid is generated from 2-ketoglutarate by the enzymatic action of hydroxyacid-oxoacid transhydrogenase but the role of D-2-hydroxyglutaric acid in normal metabolism remains undefined (Figure 97-7) (78).

**97.2.3.1 Clinical Course.** Variable clinical symptoms have been described in patients with D-2-hydroxyglutaric aciduria. In one large survey of 17 patients, 10 had a severe early-infantile-onset encephalopathy characterized by dysmorphic features, epilepsy, hypotonia, cerebral visual failure, and little development. In addition, five of these patients had cardiomyopathy (79). Dysmorphic features described include coarse facial appearance, flat face, broad nasal bridge, upturned nose, and simple and anteverted ears (80). Seven patients had a much milder and variable clinical picture, most often characterized by mental retardation, hypotonia, and macrocephaly.

**FIGURE 97-7** D-2-Hydroxyglutarate metabolism. D-2-Hydroxyglutarate is formed as a product of the enzyme hydroxyacid-oxoacid transhydrogenase, but the physiologic role of this metabolite remains unknown.

Asymptomatic patients have been reported (81). Defects in two enzymes have now been reported in patients with D-2-hydroxyglutaric acidemia but clinical correlations have not yet been possible. Both mild and severely affected patients have been shown to have mutations in the gene for D-2-hydroxyglutaric acid dehydrogenase, while others have mutations in the mitochondrial isocitrate dehydrogenase 2 gene (74,82,83).

**97.2.3.2 Diagnosis.** Biochemical findings include elevations of D-2-hydroxyglutaric acid in urine, plasma, and cerebrospinal fluid (CSF).  $\gamma$ -Aminobutyric acid is also elevated in CSF. Urinary citric acid cycle intermediates are variably elevated. Brain MRI in severely affected patients shows mild ventriculomegaly with enlarged frontal subarachnoid spaces and subdural effusions similar to those seen in glutaric aciduria (79). Cerebral maturation is delayed. Subependymal cysts over the head or corpus of the caudate nucleus are seen in patients <6 months of age. Elevated D-2-hydroxyglutaric acid in urine has been reported in patients with proven succinic semialdehyde dehydrogenase deficiency (84).

**97.2.3.3 Treatment.** No specific therapy is currently available for the disorder. Seizures and movement abnormalities should be treated symptomatically.

**97.2.3.4 Genetics.** The *D2HGA* gene for D-2-hydroxyglutaric acid dehydrogenase is on chromosome 2q37.3. The gene for the mitochondrial isocitrate dehydrogenase (*IDH2*) is on chromosome 15q26.1. Mutations in patients are nearly evenly divided between the two loci (74,82,83). *D2HGA* gene mutations are recessive, but *IDH2* mutations appear to be dominant.

## 97.2.4 Propionic Acidemia

Propionic acidemia, one of the more common organic acidemias, was first described in 1968 in an infant with severe metabolic acidosis, and many additional patients have since been reported. Propionyl-CoA is an intermediate in the oxidation of four amino acids (threonine, valine, methionine and isoleucine) as well as odd-chain fatty acids. Propionic acid is also absorbed from the large intestine where it is produced by propiogenic bacteria. Propionic acidemia is due to deficiency of propionyl-CoA carboxylase, a mitochondrial biotin-containing enzyme that catalyzes conversion of propionyl-CoA to D-methylmalonyl-CoA (Figure 97-5). The disorder is extremely variable and identification through newborn screening is possible.

**97.2.4.1 Clinical Course.** The disorder may present in the first week of life with feeding difficulties, lethargy, vomiting, and life-threatening acidosis, hypoglycemia, hyperammonemia, and bone marrow suppression (85,86). Severe hyperammonemia probably contributes appreciably to the encephalopathy of the acutely ill neonate, possibly because propionyl-CoA inhibits the synthesis of N-acetylglutamate, the major allosteric activator of carbamyl phosphate synthetase. Mortality in early-onset

disease is high (87). Equally common is a more chronic course, which presents in the first months of life with poor feeding and episodes of vomiting, infection-induced ketoacidosis, failure to thrive, and osteoporosis severe enough to cause pathologic fractures. Developmental retardation, which is probably due to neonatal hyperammonemia or chronic illness, is common, and metabolic strokes due to acute degeneration of the basal ganglia may occur during or between episodes of ketoacidosis (88). Cardiomyopathy, which may be rapidly fatal, occurs frequently and does not respond to carnitine (89). Pancreatitis is an increasingly recognized complication of the disease (90). Before expanded newborn screening, most patients did not survive beyond the first decade of life, with death often occurring during an episode of ketoacidosis in a chronically malnourished child. Newborn screening via tandem mass spectroscopy reliably can identify propionic acidemia before symptoms occur and a much milder clinical spectrum results. However, the specificity of moderately elevated C3 carnitine levels in newborns remains controversial.

**97.2.4.2 Diagnosis.** Urine organic acids at diagnosis show large amounts of 3-hydroxypropionic and methylcitric acids, often with propionylglycine and tiglylglycine, and abnormal ketone bodies such as 3-hydroxy-n-valeric and 3-keto-n-valeric acids. Acylcarnitine analysis by MS-MS shows increased C3 carnitine, and glycine levels are often elevated in blood and urine. Although usually not necessary, the enzyme defect can be demonstrated in many tissues, including leukocytes and cultured fibroblasts. Molecular testing is clinically available. Prenatal diagnosis has been accomplished with metabolite, enzymatic, and molecular techniques (91).

**97.2.4.3 Treatment.** Acute therapy is directed to treating shock, acidosis, hypoglycemia, and hyperammonemia with fluids, bicarbonate, glucose, and dialysis. Restriction of dietary natural protein (or of propiogenic amino acids) to amounts necessary to support normal growth and development is indicated, and usually results in natural protein intake less than 1 g/kg/day. Specialized formula restricted in isoleucine, valine, methionine, and threonine is used to provide additional protein for growth. Biotin supplementation is not clinically useful, but oral carnitine may be helpful to increase excretion of nontoxic metabolites. N-carbamylglutamate may help resolve hyperammonemia more quickly during episodes of acute metabolic decompensation (92,93). Metronidazole given on an intermittent basis decreases the load of propiogenic bacteria in the bowel. Liver transplant eliminates the risk for episodes of metabolic decompensation and can reverse cardiomyopathy (94,95).

**97.2.4.4 Genetics.** Propionic acidemia is inherited as an autosomal recessive trait. The genes encoding the  $\alpha$ - and  $\beta$ -subunits have been localized to chromosomes 13 (13q32) and 3 (3q13.3–22), respectively, and several disease-causing mutations have been identified in both genes (96–98). No one prominent  $\alpha$ -gene mutation has

atrophy, hyperkinesia, mental retardation, growth failure, central and cortical atrophy of the brain, and basal ganglia atrophy (103).

Mutations in the *CblC* gene cause combined methylmalonic acidemia and homocystinemia. *CblC* deficiency most commonly presents in infancy with severe clinical manifestations including basal ganglia necrosis, microcephaly, failure to thrive, mental retardation, retinopathy, and megaloblastic anemia. Thromboembolic events can occur because of elevated homocystine in the blood. However, patients with milder, late-onset disease have been reported (104). *CblD* mutations can cause combined disease as seen in *CblC*-deficient patients, but variants with isolated methylmalonic acidemia as well as isolated homocystinemia have been identified (105). Patients with defects in the *CblE* and *CblG* groups are deficient only in methylcobalamin biosynthesis, and have homocystinuria without methylmalonic aciduria (106). *CblF* deficiency results in defective transport of B12 out of lysosomes and a combined methylmalonic acidemia and homocystinemia (107). The clinical picture can be severe or mild.

Methylmalonic acidemia is now often identified through newborn screening by MS-MS; however, reports of the clinical efficacy of early detection have been mixed (99,108,109).

**97.2.5.2 Diagnosis.** Urine organic acids show increased methylmalonic acid and, especially in mutase-deficient patients, 3-hydroxypropionic and methylcitric acids, and tiglylglycine (99). The same abnormal ketone bodies noted in propionic acidemia are seen in this condition. Acylcarnitine analysis by MS-MS shows increased C3 carnitine, and glycine is usually elevated in blood and urine. Megaloblastosis is often observed in patients with the *cblC*, *cblD*, and *cblF* defects. The homocystinemia and homocystinuria seen in such patients is accompanied by low methionine and high cystathionine in serum and not, as in cystathionine synthetase deficiency, by high methionine and low cystathionine. Excretion of methylmalonic acid can be seen in dietary B12 deficiency but is not as pronounced as in the inherited disorders unless the vitamin deficiency is very severe (110). Differentiation among the various enzyme deficiencies often requires a combination of fibroblast enzyme analysis,

complementation studies, and molecular sequencing of candidate genes.

**97.2.5.3 Treatment.** As in propionic acidemia, treatment in episodes of acute metabolic decompensation is directed first to treating shock, acidosis, hypoglycemia, and hyperammonemia, followed by restriction of protein (specifically, propiogenic amino acids). Carnitine is used to treat secondary carnitine deficiency. Some patients treated in this manner do well, but many do not and die in early childhood, often during an episode of ketoacidosis (99). Patients with defects in cobalamin metabolism may respond partially or completely to supplementation with intramuscular hydroxycobalamin, but residual metabolic abnormalities are common. Betaine hydrochloride, which promotes conversion of homocysteine to methionine by betaine:homocysteine methyltransferase, can decrease homocystine levels in blood in patients with combined disorders. Liver transplantation in isolated mutase deficiency can reduce metabolic symptoms, and one patient with chronic renal failure was treated successfully with combined liver–kidney transplantation (111,112).

Patients with defects in adenosyl-B<sub>12</sub> biosynthesis often respond to large doses of B<sub>12</sub>. Even with treatment, however, many patients succumb to pancytopenia, renal involvement and neurologic impairment resembling hemolytic–uremic syndrome or to metabolic coma and cardiorespiratory arrest during childhood. Long-term survival does, however, occur, often with neurologic deficits. Prenatal diagnosis by metabolite, enzyme, or molecular analysis should be possible for all of the disorders.

**97.2.5.4 Genetics.** All forms of congenital methylmalonic acidemia are transmitted as autosomal recessive traits (Table 97-2). Multiple mutations in patients with all the disorders have been reported.

## 97.2.6 Glutaryl-CoA Dehydrogenase Deficiency

Glutaric acidemia (type I) was first described in 1975 in two siblings with a progressive movement disorder beginning in early childhood (113). The condition is inherited as an autosomal recessive trait and is due to deficiency of glutaryl-CoA dehydrogenase, a mitochondrial enzyme that converts glutaryl-CoA, an intermediate

**TABLE 97-2 Complementation Groups in Cobalamin Metabolic Disorders**

Metabolite Present	Cbl Complementation Group								
	A	B	C	D	D (v1)	D (v2)	E	F	G

in the oxidation of lysine, tryptophan and hydroxylysine, to crotonyl-CoA (Figure 97-9).

**97.2.6.1 Clinical Course.** Most patients with glutaric acidemia are born with relative macrocephaly, and suddenly develop hypotonia and dystonia during or after a relatively minor infection between the ages of 6 months and 3 years (114). Seizures, abnormal movements, hypoglycemia, hepatomegaly, and acidosis may be noted during the episode, and CT or MRI scans show acute striatal degeneration, with shrinkage of the caudate and putamen. Less common is a more chronic course in which dystonia and athetosis develop gradually during the first years of life (115). Fatty changes in the viscera, and gliosis and neuronal loss in the putamen and lateral aspects of the caudate, have been described at autopsy. Perhaps 5% of enzyme-deficient individuals remain asymptomatic. Diagnosis through expanded newborn screening with MS-MS reduces the risk for acute metabolic episodes and chronic neurologic damage (116,117).

**97.2.6.2 Diagnosis.** Type 1 glutaric acidemia is caused by a deficiency of glutaryl-CoA dehydrogenase. In most instances glutaric and 3-hydroxyglutaric acids are increased in urine; acylcarnitine analysis by MS-MS shows increased glutaryl carnitine (C5 hydroxycarnitine). Serum carnitine may be low (116). Some patients have easily detectable abnormal organic aciduria only when they are ill, and a few have so little glutaric aciduria even when ill that they are very difficult to detect with organic acid and/or acylcarnitine analysis. Diagnosis of such patients may require measurement of glutaric and 3-hydroxyglutaric acid in serum or urine by stable isotope dilution GC-MS, assay of enzyme activity in leukocytes or cultured fibroblasts, or mutation analysis. Molecular diagnosis is available. Glutaric aciduria type 2, also known as multiple acyl-CoA dehydrogenase, is a distinct disorder caused by the deficiency of either the electron transfer flavoprotein (the physiologic electron acceptor for glutaryl-CoA dehydrogenase) or its dehydrogenase and is discussed later in this chapter. Glutaric aciduria type 3 appears to be a benign phenotype of no clinical relevance caused by a deficiency of a gene of still unknown function. These individuals do not accumulate 3-hydroxyglutarate, glutaryl carnitine, or glutarylglycine in urine.

**97.2.6.3 Treatment.** Treatment of neurologically impaired patients is not usually effective, but when begun

before the onset of symptoms appears to prevent damage in two-thirds of cases (115,116). Treatment involves preventing catabolism during fasting and/or infections with intravenous fluids, electrolytes, glucose and insulin if necessary, and oral carnitine, as well as symptomatic treatment. Natural protein (or lysine) restriction is less well established in preventing symptoms, but should probably be tried. Supplementation with carnitine, creatine, glutamine, riboflavin, coenzyme Q10, pantothenic acid and  $\alpha$ -linolenic acid as a cocktail has been used extensively in the Amish population, but has not been standardized in other ethnic groups (117). Aggressive neurologic management of seizures and spasticity is necessary for patients with striatal damage.

**97.2.6.4 Genetics.** Consistent with inheritance as an autosomal recessive trait, the gene encoding glutaryl-CoA dehydrogenase is located on chromosome 19 (19p13.2). Many disease-causing mutations have been identified, but none is common except in inbred populations (118,119). A common Amish isolate has been described (117). Prenatal diagnosis is possible by enzyme assay in cultured amniocytes or chorionic villus samples, by mutation analysis, or by demonstrating large amounts of glutaric acid in amniotic fluid (118). Glutaric aciduria type 3 in the Amish population is caused by mutations in the C7orf10 gene on chromosome 7p14.

## 97.2.7 Mevalonate Kinase Deficiency

Mevalonic acidemia is caused by a deficiency of mevalonate kinase, an enzyme involved in the biosynthesis of cholesterol and nonsterol isoprenes from 3-hydroxy-3-methylglutaryl-CoA, and is inherited as an autosomal recessive trait (Figure 97-3) (120).

**97.2.7.1 Clinical Features.** Mevalonate kinase deficiency is an extremely heterogeneous disorder (121). The most severely affected patients have had profound developmental delay, distinctive facial dysmorphism, cataracts, lymphadenopathy and hepatosplenomegaly, and have died in infancy. Less severely affected patients have had milder retardation and hypotonia, myopathy, and ataxia. All have had recurrent crises of fever, lymphadenopathy, arthralgia, subcutaneous edema, and a morbilliform rash. Neuroimaging shows

**FIGURE 97-9** Glutaryl-CoA dehydrogenase both dehydrogenates and decarboxylates the substrate. Electrons pass from the FAD of glutaryl-CoA dehydrogenase into the electron transport chain at coenzyme Q, through the ETF and ETF:QO.

progressive atrophy of the cerebellum (122). When less complete, the same enzyme defect causes hyperimmunoglobulinemia D and periodic fever syndrome, characterized by recurrent febrile episodes accompanied by lymphadenopathy, abdominal distress, joint involvement and skin lesions, but without mevalonic aciduria (121).

**97.2.7.2 Treatment.** Treatment has largely been non-specific and ineffective (121). Cholesterol restriction and use of lovastatin can worsen symptoms. Corticosteroids (prednisone 2mg/kg/day) may be helpful to reduce the duration of acute crises. Long-term administration of antioxidants such as vitamin C and ubiquinone has been proposed. A three-year-old boy with severe disease was free of symptoms for 15 months following allogeneic bone marrow transplant (123).

**97.2.7.3 Diagnosis.** Organic acid analysis shows increased mevalonic acid lactone, and mevalonic acid can then be measured in blood and/or urine by stable isotope dilution GC-MS (120). If necessary, enzyme deficiency can be demonstrated in cultured fibroblasts or lymphocytes.

**97.2.7.4 Genetics.** The gene encoding mevalonate kinase has been localized to chromosome 12 (12q24), and although several disease-causing mutations have been identified, none is common (124). Prenatal diagnosis is possible by enzyme assay in chorionic villus samples or by showing increased mevalonic acid in amniotic fluid.

### 97.2.8 L- $\alpha$ -Aminoadipic Semialdehyde Dehydrogenase Deficiency

Pyridoxine-dependent seizures were first described in the medical literature in 1954, but only recently has the cause been identified as a deficiency of the enzyme L- $\alpha$ -aminoadipic semialdehyde dehydrogenase (*ALDH7A1*), also known as antiquinin (Figure 97-10) (125,126). Multiple mutations have now been described in this gene and the clinical phenotype has expanded beyond isolated seizures (127).

**97.2.8.1 Clinical Features.** Pyridoxine-dependent seizures were originally defined as clonic seizures responsive to pyridoxine supplementation in the first month of life, but it is now clear that in atypical cases, they may begin as late as 2 years of life. The electroencephalograph (EEG) is usually abnormal and may show a burst suppression pattern. MRI of the brain may be normal or show a variety of nonspecific abnormalities (128). While seizures are usually isolated, they may occur in the context of electrolyte imbalances, infections, endocrine disturbances (including hypothyroidism and diabetes insipidus), irritability, feeding intolerance, hypotonia, and respiratory distress (127). It should thus be considered in all sick infants with seizures. L- $\alpha$ -aminoadipic semialdehyde is in equilibrium with L- $\Delta^1$ -piperidine 6-carboxylate in cells and when the latter accumulates in

2-Aminoadipic semialdehyde

**FIGURE 97-10** Pyridoxine-dependent seizures are caused by a deficiency in 2-aminoadipic semialdehyde dehydrogenase. Pyridoxine is lost from cells after it reacts nonenzymatically with L- $\Delta^1$ -piperidine-6-carboxylate, which is in chemical equilibrium with 2-aminoadipic semialdehyde.

this defect, it reacts nonenzymatically with and depletes pyridoxine phosphate (127).

**97.2.8.2 Treatment.** Rapid response of seizures to pyridoxine supplementation (50–100mg intravenous (IV)) is usual but may take up to 7 days. Patients can then be maintained on 5–10mg/kg/day per os (PO). Other antiepileptics are usually not effective and generally not necessary to control seizures.

**97.2.8.3 Diagnosis.** Pípecolic acid is elevated in the blood and CSF but is not specific to this disorder (129). Elevation of L- $\alpha$ -aminoadipic semialdehyde and its ratio to creatinine in urine is diagnostic and the level usually drops with treatment (127). CSF and blood levels of threonine, glycine, taurine, and 3-methoxytyrosine may be elevated, mimicking pyridoxine-5'-phosphate oxidase deficiency, while glycine, taurine, and glutamine are often elevated in blood. Definitive testing is through molecular analysis of the *ALDH7A1* gene. Enzyme analysis is not readily available.

**97.2.8.4 Genetics.** *ALDH7A1* is on chromosome 5q31 and the disorder is inherited in an autosomal recessive manner. Sixty-four disease-causing mutations, mostly private, have been published. Genotype/phenotype correlations have been poor (127).

### 97.2.9 Succinic Semialdehyde Dehydrogenase Deficiency

This disorder is a part of the degradation pathway of the neurotransmitter GABA but manifests with increased excretion of the organic acid 4-hydroxybutyrate in urine (Figure 97-7).

**97.2.9.1 Clinical Features.** The most frequent clinical findings in this disorder include mild to moderate global developmental delay, expressive language delay, variable mental retardation, hypotonia, dystonia, seizures, hyporeflexia, ataxia, and behavioral problems (130,131). Age of onset varies from <1 to 21 years of age. MRI of the brain typically reveals an increased T2-weighted signal of the globus pallidus, with variable involvement of white matter and the cerebellar dentate nucleus.

**97.2.9.2 Treatment.** Vigabatrin may improve ataxia and dystonia. It probably does not affect intellectual development and has been reported to both help and aggravate seizures (132,133).

**97.2.9.3 Diagnosis.** 4-Hydroxybutyrate is excreted in urine, but some extraction techniques may lead to loss of this volatile compound. If the diagnosis is suspected, additional specific metabolite analysis is warranted (134). 4-Hydroxybutyrate is also present in high concentrations in CSF. 4-Aminobutyrate and homocarnosine are also elevated in urine and CSF, and glutamine may be low. Enzyme analysis is possible but not often clinically useful. With characteristic metabolites present, it is more expedient to proceed directly to molecular testing.

**97.2.9.4 Genetics.** The gene for succinic semialdehyde dehydrogenase (*ALDH5A1*) is on chromosome 6p22. Multiple mutations have been described in patients with no common mutations (135).

## 97.3 DISORDERS OF FATTY ACID OXIDATION: INTRODUCTION

Mitochondrial fatty acid oxidation is a complex process involving transport of activated acyl-CoA moieties into the mitochondria, and sequential removal of two carbon acetyl-CoA units. It is the main source of energy for many tissues including heart and skeletal muscle and is critically important during times of fasting or physiologic stress. When the body's glycogen stores are depleted, long-chain fatty acids are mobilized from adipose tissue and taken up by liver and muscle cells. While short- and medium-chain fatty acids ( $C_4$  to  $C_{12}$ ) diffuse freely across plasma and mitochondrial membranes, the transport of longer chain species ( $C_{14}$  to  $C_{20}$ ) depends at least in part on active transport, a high-affinity mechanism of major physiological importance in skeletal muscle, liver, and adipocytes (136,137). Two additional enzymatic steps are necessary for the complete oxidation of mono- and diunsaturated fatty acids, 2,4 dienoyl-CoA reductase and an enoyl-CoA isomerase, which allow for the complete oxidation of physiologically abundant fatty acids such as linoleate ( $C_{18:2}$ ) and oleate ( $C_{18:1}$ ) (138,139). Each cycle of the pathway produces a molecule of acetyl-CoA and a fatty acid with two fewer carbons. Under physiological conditions, the latter reenters the cycle until it is completely consumed. In peripheral tissues, the acetyl-CoA is terminally oxidized in the Krebs cycle for ATP production. In the liver,

the acetyl-CoA from fatty acid oxidation can instead be utilized for the synthesis of ketones, 3-hydroxybutyrate, and acetoacetate, which are then exported for final oxidation by brain and other tissues (140). At least 25 enzymes and specific transport proteins are responsible for carrying out the steps of mitochondrial fatty acid metabolism, some of which have only recently been recognized (Figures 97-11 and 97-12) (141–143). Of these, defects in at least 22 have been shown to cause disease in humans (143).

Most patients with fatty acid oxidation defects are now identified through newborn screening by MS-MS of carnitine esters in blood spots. Unscreened patients can present throughout life. In the first week of life, cardiac arrhythmias, hypoglycemia, sudden death, and occasionally with facial dysmorphism and malformations, including renal cystic dysplasia are seen. Symptoms in later infancy and early childhood may relate to the liver or cardiac or skeletal muscle dysfunction, and include fasting or stress-related hypoketotic hypoglycemia or Reye-like syndrome, conduction abnormalities, arrhythmias or dilated or hypertrophic cardiomyopathy, and muscle weakness or fasting- and exercise-induced rhabdomyolysis. Adolescent- or adult-onset muscular symptoms, including rhabdomyolysis, and cardiomyopathy predominate.

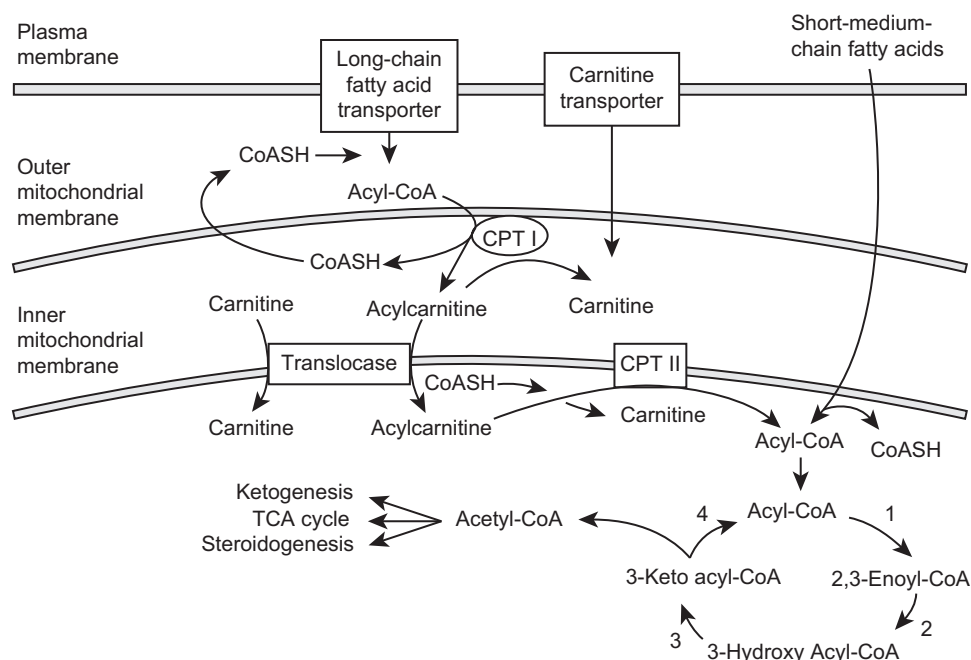

Diagnosis can usually be established even when the patient is asymptomatic, although analysis of samples during acute illness can uncover some mild cases. The most important single diagnostic test is analysis of acyl-carnitine esters in serum, plasma, or dried blood spots by tandem MS, which will identify characteristic compounds in many of these conditions. Other tests that may be useful include urine organic acids and acylglycines, free and total carnitine in serum and urine, and enzyme assays or flux studies in leukocytes or fibroblasts.

Treatment of the acute encephalopathy of hypoketotic hypoglycemia is by intravenous glucose and L-carnitine. Long-term therapy involves replenishing carnitine stores with L-carnitine, and preventing hypoglycemia. In some cases this can be done by providing a snack or glucose polymers before bedtime, but in others requires continuous intragastric feeding. Supplementation with medium-chain triglyceride (MCT) oil provides a fat source that can be utilized by patients with long-chain defects.

### 97.3.1 Long-Chain Fatty Acid Transport Defect

Two patients affected with a defect of long-chain fatty acid transport at the plasma membrane level have been reported (Figure 97-11) (3). The first patient had a history of recurrent acute liver failure and uninformative or nonspecific findings of biochemical investigations. In some of the episodes, hyperammonemia and encephalopathy were also present, but skeletal or cardiac

**FIGURE 97-11** Fatty acid transport and mitochondrial oxidation. Medium- and short-chain fatty acids do not require an active transport mechanism to reach the mitochondrial matrix. Long-chain fatty acids and carnitine are actively transported across the plasma membrane by tissue-specific transporters. Enzymes of the carnitine cycle (CPT I, translocase, and CPT II) shuttle long-chain fatty acids across the mitochondrial membranes. The fatty acid  $\beta$ -oxidation spiral includes an FAD-dependent acyl-CoA dehydrogenase step (1) followed by a 2,3-enoyl-CoA hydratase reaction (2), the NAD-dependent 3-hydroxyacyl-CoA dehydrogenase step (3) and the thiolase cleavage reaction (4). CPT, carnitine palmitoyltransferase; CoASH, free coenzyme A; TCA, tricarboxylic acid cycle.

**FIGURE 97-12** The fatty acid oxidation spiral. Multiple enzymes with chain-specific substrate utilization optima exist at each step.

myopathy was never observed. Growth and development were normal and between episodes the patient was entirely well. At 5 years of age, however, he underwent orthotopic liver transplantation following a life-threatening episode that evolved into chronic hepatic insufficiency. The second patient presented with fulminant liver failure at 4 years of age and also underwent

liver transplantation (3). Both patients are doing well several years posttransplant.

In cultured skin fibroblasts, the oxidation rates of  $C_{14}$  to  $C_{18}$  fatty acids were reduced with the severity of the defect correlating to the chain length of the substrate, but were normal in digitonin-permeabilized cells. The site of the defect was confirmed by reduced velocity of  $C_{14}$  to

C<sub>20</sub> fatty acid uptake, while the uptake of 2-deoxy-D-glucose, carnitine, and palmityl-L-carnitine were normal. The two index cases did not show correction of the uptake defect after complementation, providing additional evidence that they are affected with the same primary defect. However, any other combinations lead to normalization of oleate uptake, suggesting the possible existence of multiple defects manifesting with impaired long-chain fatty acid uptake in vitro. The gene encoding this transporter(s) has not yet been identified.

### 97.3.2 Carnitine Uptake Defect (Primary Carnitine Deficiency)

Before undergoing  $\beta$ -oxidation, free fatty acids must be activated to their corresponding acyl-CoA thioesters by long-chain specific acyl-CoA synthetases (Figure 97-11) (144). Short- and medium-chain carboxylic acids directly enter the mitochondrial matrix where they are activated. In contrast, long-chain fats are activated in the cytoplasm and require active transport into mitochondria. Transport of long-chain acyl-CoAs requires at least two enzymes, a transporter protein and the use of carnitine as an intermediate carrier molecule. Carnitine is itself transported intracellularly by a specific transporter protein (145). Two carnitine transporters have been described, one specific to the liver and a second with a more ubiquitous distribution including kidney, muscle, and fibroblasts.

Primary carnitine deficiency is caused by a defect in the sodium-dependent high-affinity carnitine transporter in the plasma membrane of muscle and kidney (but not liver) cells, which ultimately limits  $\beta$ -oxidation by reducing the entry of acyl-CoA esters into mitochondria (Figure 97-11). Free fatty acids are transported through the blood after intestinal absorption or mobilization from endogenous stores by the use of albumin as a carrier protein or in the form of triacylglycerols in lipoprotein complexes (146). Transport of free fatty acids intracellularly and through the cytoplasm is probably accomplished by a specific transport process; however, the mechanism of this step is not well characterized (147). Before undergoing  $\beta$ -oxidation, free fatty acids must be activated to their corresponding acyl-CoA thioesters. Long chain-specific acyl-CoA synthetases can be found in various subcellular locations but are thought to arise from a single gene product (144). Short- and medium-chain carboxylic acids directly enter the mitochondrial matrix where they are activated. In contrast, long-chain fats are activated in the cytoplasm and require active transport into mitochondria. Transport of long-chain acyl-CoAs requires at least two enzymes, a transporter protein and the use of carnitine as an intermediate carrier molecule. Carnitine is itself transported intracellularly by a specific transporter protein (145). Two carnitine transporters have been described, one specific to the liver and a second with a more ubiquitous

distribution including kidney, muscle, and fibroblasts. Long-chain acyl-CoAs are conjugated to carnitine by carnitine palmitoyl transferase I (CPT I) (148). This enzyme is located on the inner aspect of the outer mitochondrial membrane. Tissue-specific isoforms of this enzyme exist for muscle, liver and brain (145). Long-chain acylcarnitines are then passed to carnitine palmitoyl transferase II (CPT II) in the inner mitochondrial membrane by a translocase (149). Carnitine is freely filtered by the kidney and must be reabsorbed from the proximal tubules to preserve plasma levels. Lack of carnitine uptake in the kidney and gut causes severe hypocarnitinemia, which responds dramatically to L-carnitine.

**97.3.2.1 Clinical Course.** Patients with carnitine transporter deficiency can present with severe hypoglycemia and dilated cardiomyopathy in infancy or childhood. Alternatively, they may show onset of hypertrophic cardiomyopathy, progressive muscle weakness, and muscle lipid storage with mild elevations of creatine kinase. Carriers of OCTN2 mutations are usually asymptomatic, but hypertrophic cardiomyopathy has been reported in middle-aged individuals. Fetal hydrops secondary to this disorder have been reported (150,151). Multiple reports of asymptomatic, affected mothers have been identified when newborn screening of their affected or carrier offspring have been positive for severely low free carnitine levels (145).

**97.3.2.2 Diagnosis.** Acylcarnitine and organic acid analysis are usually normal, and diagnosis is suggested by finding extremely low levels of carnitine in serum and tissues. In fact, serum carnitine may be 1  $\mu$ mol/L or undetectable (normal = 30–70). If necessary, deficient carnitine uptake by tissues such as cultured fibroblasts can also be demonstrated. Molecular testing of the OCTN2 gene is clinically available.

**97.3.2.3 Treatment.** The response to L-carnitine supplementation is dramatic and life saving; 100 mg/kg/day can be given intravenously in emergency situations, and then administered orally on a long-term basis.

**97.3.2.4 Genetics.** The carnitine uptake defect is inherited as an autosomal recessive trait. The OCTN2 gene encoding the carnitine transporter is on chromosome 5q31, and numerous disease-causing mutations have been described (52,73). No single prominent mutation has been identified. Prenatal diagnosis can be accomplished by showing deficient carnitine uptake in cultured amniocytes or molecular testing when mutations in the proband are known (10).

### 97.3.3 Defects of Fatty Acid Entry into Mitochondria (The Carnitine Cycle)

Short- and medium-chain fatty acids are thought to enter mitochondria directly, but mitochondrial uptake of fatty acids longer than C10–12 requires esterification to an acyl-CoA, and the concerted action of CPTs I and II, and carnitine–acylcarnitine translocase (Figure 97-11). CPT I

in the outer mitochondrial membrane first transfers the acyl moiety from CoA to carnitine, and the translocase moves the acylcarnitine ester across the inner membrane in exchange for free carnitine. CPT II in the inner membrane then reconstitutes the CoA esters, which enter the  $\beta$ -oxidation spiral.

**97.3.3.1 Clinical Course.** Severe deficiency of liver CPT I is rare but more frequent milder variants have been identified in geographically restricted populations. Severe symptoms include episodic hypoketotic hypoglycemia beginning in infancy and multiorgan system failure (152–154). Cardiac symptoms are not present. Creatine kinase levels in blood are elevated in acute episodes. Organic aciduria is not prominent in this disorder, but hyperammonemia may be present. Mild CPT1 deficiency is found in high frequency in first nation populations in Canada and Alaska where it is most frequently identified through newborn screening (155,156).

Deficiency of the carnitine-acylcarnitine translocase (CACT) was initially reported in newborns who had a nearly uniform poor outcome (157–159), presenting with severe hypoketotic hypoglycemia and cardiac arrhythmias and/or hypertrophy (157,158,160,161). All have had a grossly elevated acylcarnitine to free carnitine ratio, while dicarboxylic aciduria was reported in one. Patients with a more benign clinical course have since been identified, who have responded well to modest carnitine supplementation and dietary therapy (145,162). Two affected sibs have been reported, where the younger sib was prospectively treated and has not developed any sequelae 2 years later (163). It appears that these patients have a higher level of residual enzyme activity than the more severely affected patients. Specific diagnosis of this disorder can be made via direct enzyme or molecular analysis.

CPT II deficiency is the most common of this group of disorders. It classically presents in late childhood or early adulthood as episodes of recurrent exercise- or stress-induced myoglobinuria (145,164,165). Episodes can be severe enough to lead to acute renal failure. Patients are typically well between episodes. There is no tendency to develop hypoglycemia. Weakness and muscle pain are reported. The characteristic diagnostic finding in these patients is a low total plasma carnitine level with an increased acylcarnitine fraction and no dicarboxylic aciduria. Long-chain acylcarnitines may be elevated (145). A more severe variant of CPT II deficiency presenting with symptoms similar to severe CACT deficiency has been described (166,167). In these patients, the presenting symptoms were neonatal hypoglycemia, hepatomegaly, and cardiomyopathy. Several polymorphic variants in the CPT gene have been associated with an adverse neurologic outcome in influenza encephalitis in Japan.

**97.3.3.2 Diagnosis.** The serum acylcarnitine profile is usually normal in CPT I deficiency, but acylcarnitine levels are low. CPT II and translocase deficiency can be identified but not distinguished from each other by

biochemical testing, both showing elevated C16 esters. The acylcarnitine profile may be normal in milder disease. Urine organic acids either are normal or show mild dicarboxylic aciduria. Blood amino acids are usually normal. Free carnitine in serum is two to three times normal in CPT I deficiency, and is very low in CPT II and translocase deficiency. All three enzymes can be assayed in fibroblasts and leukocytes.

**97.3.3.3 Treatment.** Acute episodes of hypoketotic hypoglycemia should be treated with intravenous glucose-containing fluids to provide at least 8–10 mg/kg/min of glucose. Treatment of hyperammonemia may require dialysis. Ammonia conjugating agents are usually not needed as the hyperammonemia reverses with correction of the underlying metabolic process. Prevention of fasting is the mainstay of therapy in all three disorders and continuous intragastric feeding may be necessary in severe disease. Carnitine supplementation is not usually effective but should be considered when free carnitine is extremely low. Bezafibrate has been shown to induce fatty acid oxidation in cells and improve flux through fatty acid oxidation in cells from patients with residual CPT2 activity (168). A subsequent small trial (six patients) indicated improvement over a 3-year period of treatment (169). Expansion of this therapy to other long-chain fatty acid oxidation disorders may be possible.

**97.3.3.4 Genetics.** All three enzyme defects are inherited as autosomal recessive traits, and the genes *CPT1A*, *CPT2*, and *SLC25A20* (the gene for the translocase) have been localized to chromosomes 11 (11q13), 1 (1p32), and 3 (3p31.21), respectively. Disease-causing mutations have been identified in all three genes, with a relatively common mutation present in the late-onset muscular form of CPT II deficiency (170), and mild CPT1 deficiency in the Hutterite population (155). Numerous coding polymorphisms of unknown significance have been identified in the CPTII gene. Prenatal diagnosis by mutation analysis or enzyme assay on amniocytes is possible in all three conditions.

## 97.3.4 Defects of the $\beta$ -Oxidation Spiral

Once in the mitochondrial matrix, acyl-CoA esters enter the  $\beta$ -oxidation spiral in which a series of four reactions successively removes two-carbon fragments of acetyl-CoA (Figure 97-12). FAD-dependent acyl-CoA dehydrogenases first oxidize the acyl-CoA to 2,3-unsaturated (enoyl-) derivatives, and these are hydrated to 3-hydroxy esters by hydratases. Oxidation to 3-ketoacyl-CoAs by NAD-requiring hydroxyacyl-CoA dehydrogenases and removal of acetyl-CoA by 3-ketothiolases follow, and the acyl-CoA, now two carbons shorter, reenters the spiral. The acyl-CoA dehydrogenases differ from most other dehydrogenases because they utilize electron transfer flavoprotein (ETF) as a final electron acceptor, and thus can channel electrons directly into the ubiquinone pool of the

electron transport machinery by way of ETF:ubiquinone oxidoreductase (ETF dehydrogenase, ETF:QO) (171).

All the enzymes of  $\beta$ -oxidation have distinct (and often overlapping) substrate chain-length specificities. For instance, different FAD-containing dehydrogenases oxidize very-long-chain (C12–24), long-chain (C6–20), medium-chain (C4–14), and short-chain (C4–6) acyl-CoAs, and similar specificities exist for the hydratases, hydroxyacyl-CoA dehydrogenases, and thiolases. Inherited defects in almost all these enzymes have been described. As a rule, defects in long chain-specific enzymes block  $\beta$ -oxidation more completely and cause more severe clinical diseases than do deficits in the medium- and short chain-specific enzymes. Although most of these conditions were originally thought to be rare, defects in very-long-chain acyl-CoA dehydrogenase (VLCAD), medium-chain acyl-CoA dehydrogenase (MCAD), and long-chain hydroxyacyl-CoA dehydrogenase (LCHAD) are among the most common metabolic defects identified through newborn screening with tandem MS. Patients who were originally reported with long-chain acyl-CoA dehydrogenase (LCAD) deficiency have all in fact been subsequently shown to have defects of VLCAD (172). Thus no bona fide patients with LCAD deficiency are known to exist.

### 97.3.5 Very-Long-Chain Acyl-CoA Dehydrogenase and ACAD9 Deficiency

**97.3.5.1 Clinical Findings.** VLCAD deficiency can present in the newborn period with arrhythmias and sudden death, or with hepatic, cardiac, or muscle presentations later in infancy or childhood (173–177). The hepatic presentation is characterized by fasting-induced hypoketotic hypoglycemia, encephalopathy, and mild hepatomegaly, often with mild acidosis, hyperammonemia, and elevated liver transaminases. Some present with arrhythmias or dilated or hypertrophic cardiomyopathy in infancy or childhood, and some with adolescence onset of exercise- or fasting-induced muscle pain, rhabdomyolysis, elevated creatine phosphokinase, and myoglobinuria. The disorder is inherited as an autosomal recessive trait. Tendency to develop hypoglycemia decreases with age, but low-grade, chronic rhabdomyolysis with acute exacerbations is common.

ACAD9 deficiency has been reported with two distinct phenotypes. In the first publication, patients had severe recurrent hypoglycemia with hepatocellular failure reversible with administration of intravenous glucose. One set of sibs also had cardiomyopathy (178). All reported patients appeared to have null mutations as indicated by lack of enzyme antigen. The deficiency has also been reported in patients with a deficiency of complex I of the respiratory chain apparently because of a second function for ACAD9 as a complex I assembly or stability factor (179,180). All these patients have

had point mutations, a finding that may be integral to determining the clinical picture. In fact, both phenotypes can be explained by the existence of a multifunctional protein complex within mitochondria that contains both the respiratory chain and fatty acid oxidation enzymes providing close physical and functional relationships between the two pathways (181).

**97.3.5.2 Diagnosis.** Analysis of serum acylcarnitines by tandem MS usually shows elevations of saturated and unsaturated C14–18 esters in VLCAD deficiency, even between episodes. Organic acid analysis during acute episodes often shows C6, C8, and C10 dicarboxylic aciduria, but because these acids can also be seen when physiological ketosis is resolving, or following the intake of MCTs, this will not raise suspicion of disease unless C12 and C14 dicarboxylic acids are also present. Free carnitine in serum is usually low. If necessary, enzyme deficiency can be demonstrated in fibroblasts or leukocytes. Molecular testing is readily available. VLCAD deficiency is now most frequently diagnosed by newborn screening with tandem MS. No consistent specific biochemical markers in blood or urine have been identified in patients with ACAD9 deficiency. Liver acylcarnitine profile has been reported to be abnormal with an excess of unsaturated compared to saturated species.

**97.3.5.3 Treatment.** Acute management of VLCAD deficiency involves administration of high infusion of high rates of glucose-containing intravenous fluids to give 8–10 mg/kg/min of glucose. Chronic management is somewhat controversial (182,183). Avoiding fasting and maintaining a high carbohydrate intake are clearly indicated, and continuous intragastric feeding may be necessary to achieve this goal, especially overnight. MCTs, whose oxidation does not involve VLCAD, can be administered to provide calories but should not be used until a diagnosis of MCAD deficiency has been excluded. However, safe fasting intervals, the use of oral carnitine, and substitution in the diet of the experimental medium-chain oil triheptanoin are more controversial. As with CPT2 deficiency, bezafibrate has been suggested as a possible means of increasing activity in patients with partially stable mutations and residual enzyme activity (168). Treatment of ACAD9 deficiency remains uncertain because of its infrequency. Institution of high glucose infusion is warranted if hypoglycemia or elevated liver enzymes are elevated, but the need for chronic management when well has not been demonstrated.

**97.3.5.4 Genetics.** The ACADVL gene has been cloned and localized to chromosome 17 (17p13), and although several disease-causing mutations are known, there is no single prominent mutation. In general, the more severe defects cause the most severe and early presenting clinical disease (5). Prenatal diagnosis is possible through enzyme assay in cultured amniocytes, by demonstrating abnormal metabolism of stable isotopically labeled palmitate by amniocytes (51), and by mutation analysis (4).

The *ACAD9* gene is on chromosome 3q21.3. There have been no reported cases of prenatal diagnosis.

### 97.3.6 Medium-Chain Acyl-CoA Dehydrogenase Deficiency

**97.3.6.1 Clinical Findings.** The most common of the fatty acid oxidation disorders, MCAD deficiency, historically most frequently presented during the first 2 years of life with episodes of fasting-induced vomiting, hepatomegaly, hypoketotic hypoglycemia, and lethargy progressing to coma and seizures (184). Blood levels of ammonia, uric acid, liver transaminases, and creatine phosphokinase may be elevated during acute episodes, and liver biopsy shows microvesicular steatosis. Autopsy shows fatty infiltration of the liver, renal tubules, and heart and skeletal muscle (185,186). The disorder was often misdiagnosed as Reye syndrome or sudden infant death syndrome, because the initial episode was fatal in about 25% of cases. Diagnosis through clinical symptoms is now rare as the disorder is readily identified through newborn screening by tandem MS. Patients thus identified are typically well, although at risk for hypoglycemia with intercurrent illness, and fatalities are a rarity. A few enzyme-deficient individuals born prior to newborn screening have had their first presentation in adolescence or adult life and some have remained asymptomatic (187).

**97.3.6.2 Diagnosis.** Analysis of serum acylcarnitines by tandem MS shows elevations of C8, C8:1, and C10:1 esters even between episodes (188). The same abnormalities are identified through newborn screening. The C6, C8, and C10 dicarboxylic aciduria that occurs during acute episodes often should raise suspicion of the disease and biochemical confirmation can be obtained by measurement of hexanoylglycine and suberylglycine in urine. Phenylpropionylglycine in urine will be elevated if the gut has been colonized by adult-type flora (189), but can be missed by all but the most sensitive techniques. Free carnitine in serum is usually low. Enzyme deficiency can be shown in fibroblasts or leukocytes, but molecular diagnosis is more readily available and often faster.

**97.3.6.3 Treatment.** Treatment of acute episodes in MCAD deficiency is primarily supportive and aimed at quickly reversing the catabolic state that is responsible for stimulating the pathways of lipolysis and fatty acid oxidation (183,190). Hypoglycemia should be corrected with bolus administration of intravenous dextrose. Continuous infusion of dextrose should then be given at a rate that maintains plasma glucose levels at, or slightly above, the normal range in order to stimulate insulin secretion and suppress adipose tissue lipolysis. Specific therapy for the mild hyperammonemia that may be present during acute illness has not usually been required. Cerebral edema has occurred during treatment in some patients with severe coma, possibly as a late reflection of acute brain injury from hypoglycemia, toxic effects of fatty acids, or

ischemia. Recovery from the acute metabolic derangements associated with coma may require more than a few hours, but is usually complete within 12–24 h, except where serious injury to the brain has occurred. Long-term management consists of dietary therapy to prevent excessive periods of fasting that can lead to coma. Overnight fasting in infants should be limited to no more than 8 h. A duration of 12 h is probably safe in children >1 year of age (191). Home blood glucose monitoring is not useful because symptomatic illness can begin before hypoglycemia has occurred. Although it is reasonable to modestly reduce dietary fat, because this fuel cannot be used efficiently in MCAD deficiency, patients appear to tolerate normal diets without difficulty, and severe restriction of fat intake may be unnecessary. Formulas containing MCT oil should be avoided. Although patients with MCAD deficiency and other acyl-CoA oxidation defects have secondary carnitine deficiency, the use of carnitine supplementation in these disorders is controversial (183,190). Some investigators suggest 50–100 mg/day of oral carnitine but its utility is unproven.

**97.3.6.4 Genetics.** The *ACADM* gene is on chromosome 1 (1p31), and MCAD deficiency is inherited as a recessive trait. The vast majority of patients with MCAD deficiency have a single common missense mutation: an A-to-G transition at cDNA position 985, which changes a lysine residue to glutamate at amino acid 329 of the MCAD precursor protein (192). The mutated amino acid is far removed from the catalytic site of the enzyme but appears to make the protein unstable by interfering with intramitochondrial folding and assembly of the nascent peptide (193). Preventing this misfolding offers an opportunity for development of new therapeutic agents for MCAD deficiency (194). The A985G mutation accounts for approximately 90% of the mutant alleles in MCAD deficiency (192). Approximately 70% of patients are homozygous for the A985G mutation. Most of the remaining patients are compound heterozygotes for the A985G allele in combination with one of several rarer mutations. Thus, only a small percentage of MCAD patients do not have at least one A985G allele. The unusually high frequency of a single common mutation has made molecular diagnosis especially valuable in MCAD deficiency. As more information accumulates from patients identified through newborn screening, correlation of phenotype with genotype is becoming clearer. Patients with the common mutation accumulate the highest levels of metabolites in the newborn period and are probably at risk for more severe disease than are many other mutations (195).

### 97.3.7 Short-Chain Acyl-CoA Dehydrogenase Deficiency

**97.3.7.1 Clinical Findings.** A number of patients with SCAD deficiency have been reported (196,197). Reported clinical findings have included episodes of intermittent

metabolic acidosis, neonatal hyperammonemic coma, neonatal acidosis with hyperreflexia, multicore myopathy, and infantile-onset lipid storage myopathy with failure to thrive, and hypotonia. Hypoglycemia is a rare finding in this disorder. The characteristic metabolites of ethylmalonic and methylsuccinic acids of SCAD deficiency were also detected in individuals with normal SCAD activity in fibroblasts (198,199). Subsequently, it was demonstrated that the presence of one of two relatively common variants of SCAD (625 G>A and 511 C>T) predisposes to excessive ethylmalonic acid production. In general, it is clear that the vast majority of patients with complete SCAD deficiency identified through newborn screening have been well, while a variety of symptoms continue to be ascribed to the deficiency in patients identified through clinical testing later in life (197,200). The full clinical spectrum of this deficiency, and the clinical relevance of the common polymorphisms, remains to be defined (201,202).

**97.3.7.2 Diagnosis.** Butyrylcarnitine in blood is elevated in complete SCAD deficiency and less reliably so in the presence of the common polymorphism. Urine ethylmalonic acid can be elevated in both clinical settings but is not specific for SCAD deficiency. Fibroblast enzyme analysis and acylcarnitine profile will identify the deficiency but may be normal in the presence of just the common polymorphisms. Molecular testing is clinically available.

**97.3.7.3 Treatment.** The need for specific dietary or supplement therapy is not supported by current literature (196). Since ethylmalonic and butyric acids are organic acids, it seems prudent to caution parents to be alert for the development of signs of acidosis during intercurrent illness and seek emergency care if they develop.

**97.3.7.4 Genetics.** The *ACADS* gene is located at chromosome 12q24.31. The two common variants (625 G>A and 511 C>T) can be present in as many as 35% of Caucasians. A common inactivating mutation has been described in the Ashkenazi Jewish population. Multiple other private inactivating mutations have been reported, as have combinations of an inactivating mutation with one of the polymorphisms in trans.

### 97.3.8 Trifunctional Protein and Long-Chain 3-Hydroxyacyl-CoA Dehydrogenase Deficiency

Several chain length-specific NAD-dependent 3-hydroxyacyl-CoA dehydrogenases catalyze the oxidation of 3-hydroxyacyl-CoA esters to 3-ketoacyl esters. LCHAD acts on hydroxyacyl-CoAs longer than C8. LCHAD and long-chain enoyl-CoA hydratase activities are carried out on the  $\alpha$ -subunit of the mitochondrial trifunctional protein, and long-chain  $\beta$ -ketothiolase activity is carried out on the  $\beta$ -subunit. LCHAD deficiency can exist alone, or together with deficiency of the other two enzymes.

**97.3.8.1 Clinical Findings.** Patients with a deficiency of this enzyme tend to fall into two clinical subclasses (203–207). One group presents primarily with symptoms of cardiomyopathy, myopathy, and hypoglycemia. Peripheral neuropathy and recurrent myoglobinuria may be present. These patients are deficient in all three enzymatic activities of the trifunctional protein. The other group, deficient only in LCHAD activity, has hepatocellular disease with hypoglycemia with or without pigmentary retinopathy. Cholestasis and fibrosis may also be present (208). Considerable overlap in these groups has been described, however, and LCHAD deficiency has also been reported in patients with recurrent Reye syndrome-like symptoms and in sudden infant death (209). Milder cases with adolescent onset of recurrent rhabdomyolysis have been reported (210). Fetal LCHAD deficiency frequently causes acute fatty liver or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) in the (heterozygous) mother during pregnancy, especially when one or both mutant alleles in the fetus is E474Q (211).

**97.3.8.2 Diagnosis.** Acylcarnitine analysis by tandem MS is usually diagnostic including in the newborn period, and shows elevated saturated and unsaturated C16 and C18 hydroxyacylcarnitines. Organic acid analysis often shows elevated C6–14 3-hydroxydicarboxylic acids, but the same abnormalities have been seen in patients with respiratory chain defects and glycogenoses, and are not specific. The enzyme defect can be demonstrated in fibroblasts and leukocytes and, for prenatal diagnosis, in amniocytes.

**97.3.8.3 Treatment.** Therapeutic options and controversies parallel those for VLCAD deficiency (143,182,183, 212). In addition, docosahexaenoic acid, a polyunsaturated C20 acid, has been proposed to slow down the development of retinitis but remains under investigation (213).

**97.3.8.4 Genetics.** LCHAD deficiency, whether isolated or part of trifunctional protein deficiency, is inherited as an autosomal recessive trait, as the genes for both subunits (*HADHA* and *HADHB*) are located on chromosome 2 (2p24.1–23.3). Several disease-causing mutations have been identified, and most affect the  $\alpha$ -subunit. One of these, E510Q (E474Q in the mature subunit), accounts for nearly 90% of mutant alleles in patients of European extraction with isolated LCHAD deficiency (214). Defects in the  $\beta$ -subunit tend to destabilize the trifunctional protein resulting in the multiple enzymatic deficiencies seen in some patients (207,215–217). Prenatal diagnosis can be made by enzyme assay in amniocytes or chorionic villus samples or, when appropriate, by mutation analysis, and on occasion will be indicated to avoid the complications of pregnancy.

### 97.3.9 Short-Chain L-3-Hydroxyacyl-CoA Dehydrogenase Deficiency

Short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD) catalyzes the NAD-dependent oxidation of

3-hydroxyacyl-CoA for C4 to C10 substrates. Deficient patients present with hypoketotic hypoglycemia associated with hyperinsulinism, reduced SCHAD activity in fibroblast mitochondria, and mutations in the *HADHSC* gene (218–220). Several other patients with abnormal metabolite or enzymatic studies suggestive of SCHAD deficiency have been reported, but as SCHAD gene sequencing was normal, the nature of their disorders remains unclear.

**97.3.9.1 Diagnosis.** A biochemical diagnosis is based on the findings of marked ketotic C8 to C14 3-hydroxy dicarboxylic aciduria. SCHAD activity in cultured skin fibroblasts may or may not be abnormal. Characteristic metabolic findings in patients with hyperinsulinemic hypoglycemia should trigger gene sequencing studies (218–220).

**97.3.9.2 Treatment.** Patients with hyperinsulinism may exhibit improved glucose homeostasis with diazoxide therapy. No specific metabolic interventions beyond avoidance of fasting and IV hydration with glucose containing solutions during illness have been reported.

**97.3.9.3 Genetics.** The genetic nomenclature for SCHAD is somewhat confusing. The gene defective in patients with hyperinsulinism is referred to as *HADHSC* in the literature but is designated as *HADH* in GenBank. It is located on chromosome 4q22–q26 and mutations in patients have been described. An enzyme designated MSCHAD in the literature is likely different than the one defective in hyperinsulinism patients, but also is identified as *HADH* in GenBank. No gene mutations have yet been identified in patients with metabolic findings of SCHAD deficiency but without hyperinsulinism, suggesting these individuals in fact have a different disorder.

### 97.3.10 Medium-Chain 3-Ketoacyl-CoA Thiolase Deficiency

The first confirmed case to be reported was a Japanese male neonate who died shortly after presenting at 2 days of age with vomiting, dehydration, metabolic acidosis, liver dysfunction, and terminal rhabdomyolysis with myoglobinuria (221). Urine organic acid analysis revealed ketotic lactic aciduria and significant C6 to C12 dicarboxylic aciduria, with strikingly elevated C10 and C12 species. In skin fibroblasts, palmitate oxidation was normal, octanoate oxidation was reduced to 31% of controls, and there was an isolated deficiency of medium-chain 3-ketoacyl-CoA thiolase activity, a result supported by the finding of a reduced protein signal by immunoprecipitation. Additional patients presented with variable but nevertheless typical symptoms of a fatty acid oxidation disorder (fasting intolerance, cardiomyopathy, and sudden death in one case) (222,223). Unfortunately, in vitro functional or molecular confirmation is not readily available.

### 97.3.11 Multiple Acyl-CoA Dehydrogenase Deficiency/Glutaric Acidemia Type II

Electrons from the acyl-CoA dehydrogenases involved in mitochondrial fatty acid and amino acid oxidation are transferred from their FAD coenzymes to coenzyme Q in the respiratory chain via ETF and ETF:QO. Defects in ETF and ETF:QO cause multiple acyl-CoA dehydrogenase deficiency, often called glutaric acidemia type II because of one of the characteristic metabolites that accumulates.

**97.3.11.1 Clinical Findings.** Glutaric acidemia type II was first described in 1976 in a baby who died at 3 days of age with severe hypoglycemia, metabolic acidosis, and the smell of sweaty feet, and many additional patients have since been described. Clinical manifestations are extremely heterogeneous (224); Frerman, 1988 #9910. A neonatal form can be seen with severe hypotonia, dysmorphic features, and cystic kidneys. These infants also exhibit metabolic acidosis and hypoglycemia. Milder variants are common, presenting with nonspecific neurological signs, lipid storage myopathy, fasting hypoketotic hypoglycemia, and/or intermittent acidosis. In some patients, only fasting hypoketotic hypoglycemia and/or intermittent acidosis is seen and can be of late onset (202,224). In these cases, the organic acid profile in times of illness is usually dominated by ethylmalonic and adipic acids, leading to an alternate name of ethylmalonic-adipic aciduria for this disorder. Structural brain abnormalities are common including agenesis of the cerebellar vermis, hypoplastic temporal lobes, and focal dysplasia of the cerebral cortex (225). Neuronal migration abnormalities may be present. Riboflavin-responsive mutations in the *ETFDH* gene have been reported (226).

**97.3.11.2 Diagnosis.** Organic acid analysis usually shows increased ethylmalonic, glutaric, 2-hydroxyglutaric, and 3-hydroxyisovaleric acids, together with C6, C8, and C10 dicarboxylic acids and isovalerylglycine, and acylcarnitine analysis by MS-MS shows glutaryl carnitine, isovalerylcarnitine, and straight-chain esters of chain length C4, C8, C10, C10:1, and C12. Serum carnitine is usually low, and serum sarcosine is often increased in patients with mild disease. Enzyme or immunoblot analyses, if necessary, will show that some patients are deficient in ETF, and that others are deficient in ETF:QO. Molecular testing is typically more readily available.

**97.3.11.3 Treatment.** Patients with complete defects often die during the first weeks of life, usually of conduction defects or arrhythmias, but those with incomplete defects can survive well into adult life. As in other fatty acid oxidation disorders, treatment relies on the avoidance of fasting, sometimes with continuous intragastric feeding, and carnitine to replenish lost stores. Riboflavin is usually given, and appears to have helped some

patients. Carnitine supplementation (100 mg/kg/day) will increase metabolite excretion and should be used.

**97.3.11.4 Genetics.** ETF and ETF:QO deficiencies are both inherited as autosomal recessive traits, and the genes encoding ETF:QO and the  $\alpha$ - and  $\beta$ -subunits of ETF have been mapped to chromosome 4 (4q32>ter), 15 (15q23–25), and 19 (19q13.3), respectively. Disease-causing mutations have been identified in all three genes, but only in the *EFTA* gene is there a common mutant allele (T266M) (227). Severe forms of the disease have been diagnosed in utero by demonstrating increased amounts of glutaric acid in amniotic fluid (228,229), and in some cases renal cysts have been seen in the fetus on ultrasound examination (230).

### 97.3.12 Disorders of Ketone Body Metabolism

**97.3.12.1 Clinical Findings.** Deficiency of the mitochondrial acetoacetyl-CoA thiolase (also known as  $\beta$ -ketoacyl-CoA thiolase) and 3-hydroxy- and 3-methylglutaryl-CoA lyase are shared disorders between ketone body metabolism and isoleucine degradation. They are discussed with the organic acidemias. Succinyl-CoA: 3-ketoacid CoA transferase (SCOT) functions in conjunction with mitochondrial acetoacetyl-CoA thiolase to generate ketones in extrahepatic tissues. SCOT deficiency presents as persistent ketonuria in the first 1–2 years of life, while acetoacetyl-CoA thiolase deficiency presents with variable clinical symptoms and exaggerated ketoacidosis in response to minor physiologic stress (231–233). HMG-CoA synthase deficiency has been reported in eight patients who presented with coma, hypoglycemia and dicarboxylic aciduria with very low ketones (234–236). Their acylcarnitine profiles were reported as normal.

**97.3.12.2 Treatment.** Treatment for most of the ketone body synthesis disorders is essentially supportive. Maintaining adequate hydration during intercurrent illness minimizes symptoms. HMG-CoA lyase deficiency can present with life-threatening hypoglycemia and hyperammonemia and must be treated aggressively (see Organic Acidemias in this chapter).

**97.3.12.3 Genetics.** Multiple mutations in the succinyl-CoA: 3-ketoacid CoA transferase gene (also called 3-oxoacid CoA transferase; OXCT1; chromosome 5) have also been described in patients with enzymatic deficiency. The HMG-CoA synthase gene (*HMGCS2*) is on chromosome 1 and gene mutations in patients have been identified (234–236).

## Biography

Dr Vockley is Professor of Pediatrics, School of Medicine; Professor of Human Genetics, Graduate School of Public Health; and Chief of Medical Genetics, Children's Hospital of Pittsburgh. He received his undergraduate degree at Carnegie-Mellon University in Pittsburgh, Pennsylvania, and received his degree in Medicine and Genetics from the University of Pennsylvania School of Medicine in Philadelphia, Pennsylvania. He completed his pediatric residency at the University of Colorado Health Science Center, and his postdoctoral fellowship in Human Genetic and Pediatrics at Yale University School of Medicine in New Haven, Connecticut. Before assuming his current position in Pittsburgh, Dr Vockley was Chair of Medical Genetics in the Mayo Clinic School of Medicine.

Dr Vockley is internationally recognized as a leader in the field of inborn errors of metabolism. His laboratory has been responsible for identifying multiple new disorders, many of them defects in mitochondrial energy and amino acid metabolisms, and he has published over 140 scientific articles in peer review journals. His current research focuses on the molecular architecture of mitochondrial energy metabolism, in which he is breaking new ground in describing the role of dysfunction of mitochondrial energy metabolism in such common conditions as diabetes, obesity, and Alzheimer disease. Dr Vockley serves on numerous national and international scientific boards including the Advisory Committee (to the Secretary of Health and Human Services) on Heritable Disorders in Newborns and Children where he is chair of the technology committee. He also serves as chair of the Pennsylvania State Newborn Screening Advisory Committee and the American College of Medical Genetics Therapeutics Committee. He is a past president of the International Organizing Committee for the International Congress on Inborn Errors of Metabolism and the Society for the Inherited Metabolic Disorders (SIMD).

Dr Vockley is the cofounder and editor of the North American Metabolic Academy established by the SIMD to help educate the next generation of metabolic physicians in the United States, and serves as associate editor for the journals *Molecular Genetics and Metabolism* and *The Journal of Inherited Metabolic Disorders*. Dr Vockley was recognized in 2002 as the Research Educator of the Year while at the Mayo Clinic. At the University of Pittsburgh, Dr Vockley teaches in both the Medical School and Graduate School of Public Health. Dr Vockley has mentored numerous PhD candidates, postdoctoral fellows, and undergraduate in their research.

## Vitamin D Metabolism or Action

*Elizabeth A Streeten*

Associate Professor of Medicine, Division of Endocrinology, Diabetes, and Nutrition,  
University of Maryland School of Medicine, Baltimore, MD, USA

*Michael A Levine*

Medical Director, Center for Bone Health at the Children's Hospital of Philadelphia, PA, USA

### 98.1 HISTORY

Rickets and osteomalacia were widespread problems until the discovery of the calciferols (1), after which they were used for prevention and treatment. However, some cases did not respond to the usual doses of calciferols, and multiple genetic and other causes were subsequently recognized. In 1937, Albright reported detailed studies of a child with this problem and suggested a hereditary resistance to the actions of calciferols (2). Rickets resistant to calciferols was subsequently recognized as a common cause of hereditary dwarfism. Most hereditary cases showed biochemical features different from those of calciferol nutritional deficiency, and are now classified as phosphate diabetes or X-linked hypophosphatemia.

In 1961, Prader et al. (3) characterized a distinctive form of hereditary rickets that they called pseudodeficiency rickets. Features that clearly distinguished pseudodeficiency rickets from X-linked hypophosphatemia were hypocalcemia, the potential for complete remission with high doses of calciferols, and an autosomal transmission pattern.

In 1971,  $1\alpha,25(\text{OH})_2\text{D}_3$  was shown to be the active metabolite of vitamin  $\text{D}_3$  that accumulated in the nuclei of target tissues (4–6). This discovery quickly led to the development of methods to measure active metabolites in blood, characterization of defects in  $1\alpha,25(\text{OH})_2\text{D}$  synthesis and action, and an understanding of the roles of  $1\alpha$ -hydroxylated and other analogs for therapy. Fraser et al. (7) showed that pseudodeficiency rickets in one patient was corrected with physiologic doses of  $1\alpha,25(\text{OH})_2\text{D}_3$ ; they suggested that this disorder represented a defect in  $25(\text{OH})\text{D}_3$   $1\alpha$ -hydroxylase enzyme. Subsequently, Brooks et al. (8) described a patient with similar clinical features but high serum levels of  $1\alpha,25(\text{OH})_2\text{D}$  before and during treatment; they suggested that pseudodeficiency rickets be classified as type I (deficient production of  $1\alpha,25(\text{OH})_2\text{D}$ ) or type II (impaired end-organ response to  $1\alpha,25(\text{OH})_2\text{D}$ ).

Recent identification of patients with novel defects in the activation (9) or action of (10) vitamin D have further extended the molecular pathophysiology of this disorder.

### 98.2 NORMAL PHYSIOLOGY OF CALCIFEROLS

#### 98.2.1 Vitamin D Sources

Cholecalciferol (vitamin  $\text{D}_3$ ) (11) is a secosteroid produced via opening of the B-ring of 7-dehydrocholesterol (Figure 98-1). In humans, this reaction is driven by ultra-violet radiation (from sunlight) in the basal layers of the epidermis (12). Skin pigment can decrease the amount of cholecalciferol synthesized in response to UV radiation (13). In addition, with aging, vitamin D synthesis in skin is reduced and requires more prolonged exposure to UV radiation (14). Ergocalciferol (vitamin  $\text{D}_2$ ) is produced by opening the B-ring of ergosterol, a sterol found in plants and fungi. Plants do not contain important amounts of ergocalciferol but this chemical is synthesized in bulk for use as a nutritional supplement. Humans obtain calciferols either endogenously through metabolism of precursors in the skin or exogenously as a dietary component or supplement. The metabolism and actions of vitamin  $\text{D}_3$  and  $\text{D}_2$  are similar in humans but  $\text{D}_3$  is slightly more effective than  $\text{D}_2$  in correcting vitamin D deficiency and maintaining normal circulating levels of  $25(\text{OH})\text{D}$  (15–18).

#### 98.2.2 Vitamin D 25-Hydroxylation

Cholecalciferol and ergocalciferol have little or no direct biological activity on vitamin D target cells or receptors. They must be hydroxylated at positions 25 and  $1\alpha$  to become maximally active (Figure 98-2). The initial hydroxylation at carbon-25 is carried out primarily in

the liver by a microsomal cytochrome P450 mono-oxygenase. The 25-hydroxylation of vitamin D is not highly regulated; the principal determinant of the rate of this reaction is the circulating level of its substrate, vitamin D.

The identity of the microsomal P450 enzyme CYP2R1 as the primary hepatic 25-hydroxylase (19) was confirmed via molecular studies of two brothers with congenital rickets who were previously hypothesized to have a putative deficiency of 25-hydroxylase (9). Both these brothers were found to be homozygous for a transition mutation in exon 2 of CYP2R1 on chromosome 11p15.2, which causes an amino acid substitution that eliminates ability of the enzyme to 25-hydroxylate substrate vitamin D<sub>3</sub> (20). Activity of CYP2R1 is constitutive, and therefore, production of 25(OH)D from precursors D<sub>2</sub> and D<sub>3</sub> is substrate dependent.

In addition to liver, CYP2R1 is also expressed in keratinocytes (21), testis (22) and to a minor degree in numerous other tissues (23). Additional less-important cytochrome P450 enzymes with 25-hydroxylase function are CYP3A4, CYP27A1 and CYP2J2 (24).

### 98.2.3 1 $\alpha$ -Hydroxylation

The fate of 25(OH)D is determined by two competing enzymatic pathways. Circulating 25(OH)D can undergo transformation to the fully active form of vitamin D, 1,25(OH)<sub>2</sub>D, via a second hydroxylation performed by the 1 $\alpha$ -hydroxylase, CYP27B1 (25), that is present principally in the proximal renal tubule. Alternatively, 25(OH)D can be inactivated to a water-soluble metabolite

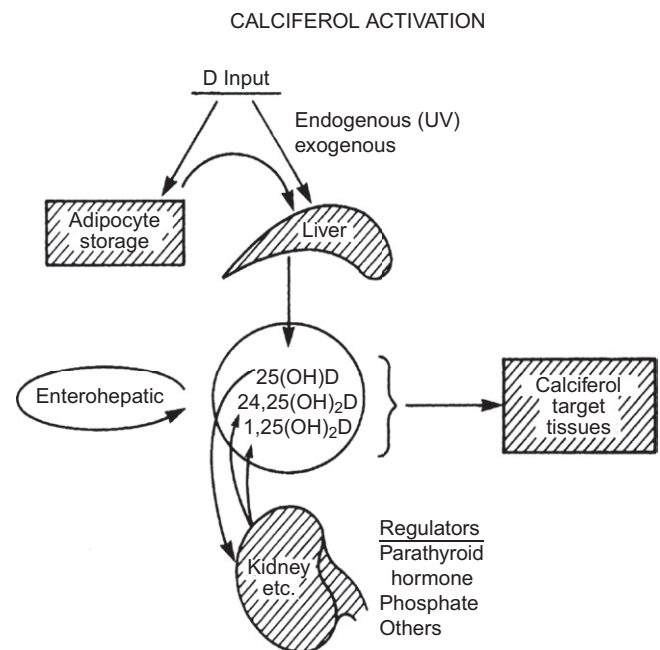

24,25(OH)<sub>2</sub>D by mitochondrial cytochrome P450 enzymes that are present in the kidney (CYP24A1) or liver and intestine (CYP3A4). The renal 1 $\alpha$ -hydroxylase is the gene product of CYP27B1, present on chromosome 12q13, and cloned in 1997 (26). Renal production is the primary source of circulating 1,25(OH)<sub>2</sub>D (27), although many nonrenal tissues also express CYP27B1, as discussed below. Renal 1 $\alpha$ -hydroxylase is the rate-limiting step in the production of serum 1,25(OH)<sub>2</sub>D and the activity of this enzyme is tightly regulated by parathyroid hormone (PTH) and the phosphotonin fibroblast growth factor 23 (FGF23). In addition, hypocalcemia and calcitonin can induce CYP27B1 expression. PTH activates transcription and activity of CYP27B1 in the renal proximal tubule through a cyclic AMP-mediated pathway (28). The enzyme is inhibited by 1,25(OH)<sub>2</sub>D, calcium, phosphate, and FGF23. Following PTH stimulation in the kidney, the nuclear orphan receptor NR4A2 is upregulated, enhancing the PTH-induced increase in CYP27B1 expression; C/ERBP $\alpha$  inhibits this transcriptional enhancement (29).

The renal 25(OH)D 1 $\alpha$ -hydroxylase enzyme contains a cytochrome P450 and reno-redoxin (30,31); dephosphorylation of the reno-redoxin component may mediate activation of the 1 $\alpha$ -hydroxylase by PTH (32).

CYP27B1 is also expressed in many nonrenal tissues, including parathyroids, (33), testis (22), prostate (34), breast (35), colon (36), pancreatic beta cells (37), endometrium (38), cervix (39), ovary (40), adipocyte (41), bone cells (both osteoblasts and osteoclasts) (42), placenta (43) and vascular endothelial (44) and smooth

muscle cells (45). Although  $1,25(\text{OH})_2\text{D}_3$  is produced in these tissues, the contribution to the circulating pool of  $1,25(\text{OH})_2\text{D}_3$  appears negligible, and in these tissues,  $1,25(\text{OH})_2\text{D}_3$  appears to play a paracrine or apocrine role. For examples, locally produced  $1,25(\text{OH})_2\text{D}$  serves as a differentiating factor for many cells. A wide variety of pathologic tissues also express CYP27B1 (including granulomas and most malignancies) and mutations of CYP27B1 in cancer tissues are thought to be one mechanism by which these tissues escape the normal constraints on their growth (46,47). Whereas in the kidney, production of  $1,25(\text{OH})_2\text{D}$  is tightly regulated by PTH and FGF23, in most nonrenal tissues, local factors regulate its production (24).

### 98.2.4 24-Hydroxylation

The primary catabolic enzyme that prevents excessive production of  $1,25(\text{OH})_2\text{D}$  is a 25-hydroxyvitamin D-24-hydroxylase, herein referred to as CYP24A1, that is expressed in the kidney. CYP24A1 is a cytochrome P450 enzyme and catalyzes the addition of a hydroxyl group on carbon 24 of the vitamin D secosteroid backbone. The human CYP24A1 gene, located on chromosome 20, was cloned in 1993 (48). CYP24A1 is one of the most inducible genes in body, and transcription can be increased 20,000-fold by  $1,25(\text{OH})_2\text{D}$  (47). This high inducibility of CYP24A1, with consequent rapid inactivation of  $1,25(\text{OH})_2\text{D}$  to the water-soluble inert metabolite  $1,24,25$ -trihydroxyvitamin D, is likely the major reason that vitamin-D intoxication is uncommon after exposure to high doses of vitamin D. The inactivation of  $1,25(\text{OH})_2\text{D}$  consists of five enzymatic steps that involve successive hydroxylation/oxidation reactions at carbons 24 and 23 followed by cleavage of the secosteroid at the C-23/C-24 bond and subsequent oxidation of the cleaved product to calcitroic acid.  $1,25(\text{OH})_2\text{D}$  can also undergo inactivation by CYP3A4-dependent 23- and 24-hydroxylations in the liver and small intestine. Both CYP24 and CYP3A4 can also inactivate  $25(\text{OH})\text{D}$ . CYP3A4 is one of the most polymorphic genes, and plays a critical role in activating and inactivating a large number of endogenous compounds and drugs. Hence, induction of CYP3A4 by drugs such as dilantin and phenobarbital likely accounts for the low circulating levels of vitamin D metabolites in individuals who receive these medications. There are many similarities between the 1-hydroxylase (CYP27B1) and 24-hydroxylase (CYP24A1) enzymes, which suggest that they share certain components. Both are mitochondrial enzymes containing cytochrome P450 (49). Both are modulated (though in opposing directions) by cAMP and  $1,25(\text{OH})_2\text{D}$  (50) and both are distributed in similar anatomical sites. The role of 24-hydroxylase has not been fully determined; it may be the only route to a group of calciferols with unique actions not obtainable with  $1,25(\text{OH})_2\text{D}$  (see later discussion in Section 98.3.11), and it might be a critical step in regulating vitamin D action via enhanced production of  $24,25(\text{OH})_2\text{D}$ ,

which reduces availability of substrate  $25(\text{OH})\text{D}$  for activation by the 1-hydroxylase. Moreover, 24-hydroxylase also limits biological activity of  $1,25(\text{OH})_2\text{D}$ : expression of the CYP24A1 gene is induced by  $1,25(\text{OH})_2\text{D}$  in target tissues (50,51), and the 24-hydroxylase shows a preference for  $1,25(\text{OH})_2\text{D}$  rather than  $25(\text{OH})\text{D}$  as substrate. These observations define a system of elegant control, in which the  $1,25(\text{OH})_2\text{D}$  hormone induces the expression of the gene encoding a key effector of its catabolic breakdown. Mouse vitamin D 24-hydroxylase has been cloned; its mRNA is most abundant in the kidney and intestine, with smaller amounts detectable in skin, thymus, bone, lung, spleen, pancreas, and heart (52).

As seen with reduced CYP27B1 expression in cancers (discussed above), increased CYP24A1 expression in cancers has been found (53–55), both leading to reduced tissue production of  $1,25(\text{OH})_2\text{D}$  and reduction in its differentiating effect on cells (53,56,57).

### 98.3 5,6-CIS-TRANS-ISOMERIZATION

$25(\text{OH})\text{D}$  may also be converted to 5,6-trans- $25(\text{OH})\text{D}$ . This pathway was initially documented in plasma from rats that were treated with pharmacologic amounts of vitamin D3 (58). The pathway is of interest because it produces a metabolite analogous to  $25(\text{OH})$ -dihydrotachysterol (Figure 98-3) (dihydrotachysterol is a synthetic calciferol analog). These metabolites have an A-ring rotated  $180^\circ$ , bringing the 3-hydroxyl group into a pseudo- $1\alpha$ -hydroxyl position. This rotation increases the biological activity and potency of the metabolite relative to the parent metabolite. 5,6-trans metabolites might have important roles in states where the renal  $1\alpha$ -hydroxylase enzyme is severely deficient. In vitro studies show that the 5,6-trans metabolites are less-potent promoters of intestinal calcium absorption (by a factor of 0.0003) than  $1,25(\text{OH})_2\text{D}_3$  (59). Numerous synthetic stereoisomers of the A-ring (60) and C-D rings (61) are now under study for potential clinical use as fully active forms of vitamin D that represent novel analogs of  $1,25(\text{OH})_2\text{D}_3$ .

**FIGURE 98-3** Steric conformation of two activated calciferol analogs.  $1\alpha, 25(\text{OH})_2\text{D}_3$  has the 5–6 double bond in cis configuration.  $25(\text{OH})$ -dihydrotachysterol has the 5–6 double bond in trans configuration; the  $180^\circ$  rotation of the A ring (lowest ring in figure) brings the  $3\beta$  hydroxyl group into a pseudo- $1\alpha$  configuration.

### 98.3.1 Vitamin D-Binding Protein in Plasma

All calciferols are fat-soluble and circulate, principally bound to an  $\alpha$ -globulin of 58 kDa (62), made in the liver called vitamin D binding protein (DBP, also known as GC-globulin or group-specific component globulin). The gene for DBP, GC, is located on chromosome 4, in the same gene cluster as the gene for albumin (63). Although GC was sequenced in 1993 (64), it was identified as a protein that binds vitamin D analogs in 1975 (65). The messenger RNA for this DBP, Gc, is homologous to that for albumin and  $\alpha$ -fetoprotein (66). DBP is a major component of plasma protein (normal concentration 10–5 M) and is one of the most highly polymorphic proteins (67), thus making it a useful genetic marker. In fact, DBP isoforms were studied as measures of genetic diversity long before a function in calciferol transport was recognized. DBP contains one high-affinity sterol-binding site with the following order of affinities:  $25(\text{OH})\text{D}_3$ -26,23-lactone >  $25(\text{OH})\text{D}$  =  $24,25(\text{OH})_2\text{D}$  >  $1\alpha,25(\text{OH})_2\text{D}$  >> vitamin D. It is a highly expressed protein with multiple functions, including transport of vitamin-D metabolites, control of bone development, binding of fatty acids, sequestration of actin, and a range of less-defined roles in modulating immune and inflammatory responses. DBP plays an important role in modulating inflammatory and immune responses as a precursor of the inflammation-primed macrophage activating factor, GcMAF (65,68).

### 98.3.2 Calciferol Turnover and Requirements

Most of the body pool of vitamin D is stored in fat, compared with 30% of  $25(\text{OH})\text{D}$  (69) and a small fraction of  $1,25(\text{OH})_2\text{D}$  (70). When present in the circulation, more than 99% of each metabolite is bound to proteins. Normal turnover of vitamin D is approximately 30  $\mu\text{g}$  per day; most of this is cleared through catabolic pathways, with only 1  $\mu\text{g}$  per day cleared as  $1,25(\text{OH})_2\text{D}$  (Table 98-1). Drugs and diseases known to induce CYP3A4 or CYP24A1 (antiseizure medications, bile acids, alcohol, hyperthyroidism) can increase clearance of  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$ .

### 98.3.3 $1,25(\text{OH})_2\text{D}$ Receptors

The biological actions of  $1,25(\text{OH})_2\text{D}$  are mediated through two different types of receptors. Conventional vitamin-D effects reflect the genomic actions, which are mediated via binding to the VDR, a high-affinity intracellular nuclear receptor that is analogous to the receptors for other steroid hormones (71). By contrast, other vitamin-D actions are mediated through binding of  $1,25(\text{OH})_2\text{D}$  to a putative plasma membrane receptor (discussed more fully under Section 98.3.5), which affects nongenomic actions of  $1,25(\text{OH})_2\text{D}$ . The genomic vitamin D receptor (VDR) is a 50-kDa protein whose sequence (72) resembles that of other members of the steroid hormone—thyroid hormone—retinoic acid receptor gene superfamily. This superfamily includes the receptors for other steroid hormones, the receptor for triiodothyronine, the receptor for retinoic acid, and a product of the *erb-a* oncogene, which acts as a regulator of gene transcription (73,74). The VDR is highly expressed in small intestine and bone, the major vitamin D target tissues, and is also present in most other tissues, including testis, ovary, pituitary, parathyroid, skin, breast, muscle, lymphocytes, some tumor cell lines (75–80) and cancers. In prostate cancer, high levels of VDR expression in tumor tissue were found to be associated with a more favorable clinical outcome (81). The VDR has a hormone-binding domain at the C-terminus for the binding of  $1,25(\text{OH})_2\text{D}$  and a DNA-binding domain with two zinc fingers at the amino terminus (82). After binding of  $1,25(\text{OH})_2\text{D}$  to the hormone-binding domain of the VDR, the  $1,25(\text{OH})_2\text{D}$ -VDR complex dimerizes with the retinoid X receptor (RXR) and the  $1,25(\text{OH})_2\text{D}$ -VDR-RXR heterodimer then binds to vitamin D-response elements (VDRE) that are present in target genes, thereby regulating gene transcription (83,84). Expression of VDR is induced by cell proliferation, by exposure to  $1,25(\text{OH})_2\text{D}$ , and by the ontogenetic state. For example, the receptor first appears in rat intestine 14 days postnatally and correlates with the onset of  $1,25(\text{OH})_2\text{D}$ -dependent calcium transport therein (85). The affinity of vitamin D compounds for the VDR correlates with their biological potency;  $1,25(\text{OH})_2\text{D}$  is the most potent natural calciferol metabolite, with an ED50

**TABLE 98-1 Serum Levels and Body Pools of Calciferol Metabolites in Adults<sup>a</sup>**

	Concentration in Serum (ng/mL)	Half-Life in Serum (Days)	Pool Size in Body (mg)	Turnover in Body Metabolite (mg/day)
D3	10 <sup>b</sup>	30	1000	30
$25(\text{OH})\text{D}$	25	15	500	15
$1,25(\text{OH})_2\text{D}$	0.03	0.2	0.5	1
$24,25(\text{OH})_2\text{D}$	1	2	10	10

<sup>a</sup>With the exception of serum concentrations, these numbers are based on limited data.

<sup>b</sup>Typical summer mean temperate climate; normal winter mean is below 0.5 ng/ml.

From Marx, S. J. Vitamin D and Other Calciferols. In *The Metabolic Basis of Inherited Disease*, 6th ed.; Scriver, C. R.; Beaudet, A. L.; Sly, W. S.; Valle, D. Eds.; McGraw Hill: New York, 1989; pp 2029.

of approximately 1/1000 that of 25(OH)D in most test systems (86). Because of differing concentration ranges for metabolites (Table 98-1), the receptor may be activated in vivo by a mixture of agonists, including 1,25(OH)<sub>2</sub>D, 25(OH)D<sub>3</sub>, and 5,6-trans-25(OH)D.

The identification of allelic variants of the VDR gene has stimulated interest in examining possible relationships between VDR genotypes and bone mineral density (87). These allelic variants, many of which are associated with polymorphisms for the recognition sites of restriction endonucleases (e.g., BsmI, TaqI, and ApaI), are distributed into five major genotypes in most populations studied (88,89). Although initial studies showed a strong association between VDR gene polymorphisms, bone mass and bone turnover (87), subsequent studies in more diverse populations have shown more conflicting results, and indicate a lesser (or inconsistent) role for VDR alleles in the determination of the heritable component of bone density and strength (reviewed in References (90,91,92a,93). The recognition that vitamin D plays a role in diverse biological processes beyond bone and mineral metabolism, such as regulation of inflammation, neoplasia, and apoptosis, has led to additional studies of possible genetic associations with the VDR. For example, recent analyses show modest (or conflicting) associations between VDR genotype and risk of some cancers (94a), height, and adiposity (95–98). The nonbone effects of vitamin D, such as its antiproliferative action in some tissues and tumors, also appear to be dependent on the presence of VDRs in the target tissue (99). (For review of associations of VDR polymorphisms and diverse diseases, see Reference (100)).

### 98.3.4 Transcriptional Effects of 1,25(OH)<sub>2</sub>D

The best characterized function of the VDR is as a ligand-dependent transcription factor. After 1,25(OH)<sub>2</sub>D binds to the VDR, the VDR forms a stable heterodimer complex with retinoid X receptors. The heterodimer binds to VDREs (83), specific DNA motifs in the promoter region of target genes, and attracts nuclear receptor coactivators and other components necessary to alter gene transcription (101,102). By this mechanism, 1,25(OH)<sub>2</sub>D alters gene transcription of many proteins. Some of the target genes are known. For example, in response to 1,25(OH)<sub>2</sub>D, cholecalciferol (see later discussion in Section 98.3.6) mRNA levels in duodenal mucosa (and in many other tissues) are increased (103), levels of mRNA encoding osteocalcin (also termed bone  $\gamma$ -carboxyglutamic acid-containing, or bone GLA protein) rise in osteoblasts (104), and levels of procollagen type I mRNA fall in parathyroid cells (105) (see later discussion in Section 98.3.6 for more details concerning the proteins encoded by some of these mRNAs). These observations have led to the identification of VDREs in the promoter regions of the osteocalcin gene (positive VDRE) and the PTH gene

(negative VDRE) that are required for these vitamin D effects. In addition to regulating traditional targets genes that are involved with calcium homeostasis, 1,25(OH)<sub>2</sub>D is now known to be an important regulator of cell differentiation and growth (see References (106,107) for review), immune responses (108) and hormone secretion from endocrine tissues such as the pancreas (109).

### 98.3.5 Nongenomic Effects of 1,25(OH)<sub>2</sub>D

1,25(OH)<sub>2</sub>D exerts some cellular effects through a mechanism that does not involve alterations in gene transcription (i.e. nongenomic pathway). Evidence for these mechanisms includes extremely rapid effects (110,111) and dependency on normal receptor genes (112). Nongenomic effects of steroid hormones in target cells are transmitted through membrane receptors that appear to be identical to classical intranuclear steroid hormone receptors (113a). Activation of this signaling pathway leads to stimulation of MAP kinase and involves cross-talk with the nuclear VDR (see References (106,114) for review) as well as interaction of membrane receptors with other proteins (e.g. ion channels) or signal transduction pathways (e.g. protein kinase C, cAMP, Ca<sup>2+</sup>, etc.). The membrane-bound VDR appears to control pathways that are important for both fracture healing and chondrocyte maturation (115,116). One nongenomic receptor has been identified, protein-disulfide isomerase-associated 2 (Pdia3, also called Grp58, ERp60, ERp61, PDI-Q2, and 1,25D3-MARRS (membrane-associated, rapid response steroid binding), a glycoprotein-specific thiol oxidoreductase that is localized to the endoplasmic reticulum (see Reference (117) for review). The gene for Pdia3 is located on chromosome 15. Pdia3 has been shown to mediate 1,25(OH)<sub>2</sub>D effects on the osteoblast in vitro, through activation of protein kinase C (118).

### 98.3.6 Calbindin and Intestinal Transport of Calcium

The most important traditional physiologic action of 1,25(OH)<sub>2</sub>D is stimulation of active calcium transport across the duodenum from lumen to bloodstream. Calcium absorption occurs predominantly in the proximal small intestine (90%), with lesser amounts absorbed through the colon (10%). In the duodenum, calcium transport is active and saturable; in the jejunum and ileum, calcium transport is passive and nonsaturable. When calcium intake is low, the active duodenal transport of calcium predominates. When calcium intake is high, passive absorption is increased (see Reference (119) for review). Calbindin (also called cholecalciferol, or vitamin D-dependent calcium-binding protein) is a vitamin D-dependent protein that binds calcium with high affinity (the calcium-binding regions are homologous to those of the calmodulin family). Calbindins are highly expressed in the intestine and kidney in the chick and mammals,

and are classified in different subfamilies as they differ in the number of  $\text{Ca}^{2+}$ -binding EF-hand sites. There are at least two *calbindin* genes; one codes for a 9-kDa protein (*calbindin-D9k*) concentrated in the duodenum, the other for a homologous 28-kDa (*calbindin-D*) protein concentrated in kidney, brain, bone, and many other tissues. There is no homology between *calbindin-D28k* and *calbindin-D9k*, apart from their calcium-binding domains (EF-hands): *calbindin-D9k* has two EF-hands, and *calbindin-D28k* has six. The *calbindin-D9k* gene is expressed in duodenal cell cytoplasm and is involved in  $1,25(\text{OH})_2\text{D}$ -mediated calcium absorption although the precise mechanism is unknown (120). *Calbindin* in the duodenum might act as a buffer of intracellular calcium (121) or as a regulator of calcium ATPase (122). *Calbindin-D9k* constitutes approximately 2% of duodenal mucosal cell protein (found only in high amounts in the duodenum) in the D-replete state, and is undetectable in duodenum in the D-deficient state.

A widespread tissue distribution of  $1\alpha,25(\text{OH})_2\text{D}$  receptors and of a family of *calbindin* proteins indicates that  $1,25(\text{OH})_2\text{D}$  may act directly in many tissues. Recent experimental evidence indicates that *calbindin-D* can inhibit apoptosis induced in varied cells, including pancreatic beta cells, renal cells, and osteoblasts, partially through its role in buffering intracellular calcium (123). Recent evidence suggests that TRPV5 and TRPV6, apical calcium channels that are colocalized in the duodenum with *calbindin*, are involved in active duodenal calcium absorption (124). There is no known regulation of passive, paracellular calcium absorption (125). Bone volume and stiffness are both increased in *calbindin-D28K* knockout mice, indicating that *calbindin* plays a significant role in skeletal remodeling (126a).

### 98.3.7 $1,25(\text{OH})_2\text{D}$ Actions on Bone

Most of the antirachitic actions of calciferols are secondary to maintenance of calcium and phosphate concentrations in extracellular fluid adequate for bone mineralization (127–129).  $1,25(\text{OH})_2\text{D}$  inhibits proliferation and collagen synthesis in fetal bone and osteoblasts (130). In osteoblast-like cells from adult humans, however,  $1,25(\text{OH})_2\text{D}$  stimulates collagen synthesis (131). Differing effects on alkaline phosphatase have been reported in several systems; however, there is general agreement that in rapidly growing osteoblast-like cells, alkaline phosphatase levels are low and that they rise in response to  $1,25(\text{OH})_2\text{D}$  (132).

In vivo and in organ culture,  $1,25(\text{OH})_2\text{D}$  is a potent activator of osteoclasts. Isolated osteoclasts, however, show no response to  $1,25(\text{OH})_2\text{D}$  (133) and contain no receptors for  $1,25(\text{OH})_2\text{D}$  (134). At least three mechanisms have been suggested to explain the ability of  $1,25(\text{OH})_2\text{D}$  to activate osteoclasts: first,  $1,25(\text{OH})_2\text{D}$  may stimulate differentiation of osteoclast precursors, related to monocytes and macrophages (135,136);

second,  $1,25(\text{OH})_2\text{D}$  may stimulate fusion and metabolism of the immediate precursor of the multinucleated osteoclast (137); and third,  $1,25(\text{OH})_2\text{D}$  might stimulate adjacent cells (138) such as osteoblasts to activate osteoclasts.  $1,25(\text{OH})_2\text{D}$  can activate cells of the osteoblast lineage, leading them to undergo shape changes and secrete collagenase and other enzymes that lyse proteins on the bone surface; they also express a factor that is termed RANK ligand (previously known as osteoclast differentiating factor, ODF). RANKL interacts with a receptor on osteoclast precursors that is identical to the receptor involved in interaction of T cells and dendritic cells called receptor activator of NF-kappa B (RANK). RANKL stimulates activation, migration, differentiation, and fusion of hematopoietic cells of the osteoclast lineage to begin the process of resorption (139,140). RANKL can also bind a protein that is produced by osteoblasts and other marrow cells called osteoprotegerin (OPG) or osteoclastogenesis inhibitory factor (141,142). OPG acts as a “decoy receptor” for RANKL and thereby inhibits osteoclast recruitment and activation (143). Recent studies have documented that transgenic mice, in which OPG has been inactivated have marked osteoporosis (144), and genetic mutations in humans that reduce expression of OPG (145,146) or activate RANK (147,148) are associated with excessive bone resorption. In vivo studies on a mouse VDR knockout model have suggested that vitamin D-mediated osteoclast formation requires the presence of osteoblasts, but normal osteoclasts can form in the absence of VDR, presumably via the influence of other agents (149).  $1,25(\text{OH})_2\text{D}$  also plays a role in osteoblast differentiation (150).

### 98.3.8 $1,25(\text{OH})_2\text{D}$ Actions on Skin and Hair

Receptors for  $1,25(\text{OH})_2\text{D}$  have been identified directly by in vivo autoradiography in basal layers of epidermis and in the outer root sheath cells of the rat hair follicle (151). The VDR is also present in human skin fibroblasts and keratinocytes (14).  $1,25(\text{OH})_2\text{D}$  inhibits proliferation of cultured human fibroblasts and promotes terminal differentiation of keratinocytes (14). These effects of  $1,25(\text{OH})_2\text{D}$  have led to the use of vitamin-D analogs in the treatment of psoriasis, a hyperproliferative disorder of the epidermis (14,152). Topical vitamin-D analogs have been developed to minimize the hypercalcemic response to vitamin-D treatment in psoriasis (153). In vitro studies have shown that  $1,25(\text{OH})_2\text{D}$  suppresses ultraviolet-induced apoptosis in cultured skin keratinocytes (154). Although not yet completely delineated,  $1,25(\text{OH})_2\text{D}$  plays a significant role in hair growth. The mammalian hair cycle requires both the VDR and the hairless (Hr) corepressor, each of which is expressed in the hair follicle. Hr interacts directly with VDR to repress VDR-targeted transcription (155). Lack of VDR or Hr results in premature apoptosis of the hair bulb during

the first catagen stage of the hair cycle, with subsequent loss of hair follicles. In nude mice with congenital alopecia and in cultured hair follicles,  $1,25(\text{OH})_2\text{D}$  stimulated hair growth (156,157). New research has shown that the effect of  $1,25(\text{OH})_2\text{D}$  on hair involves the wnt (158) and hedgehog (159) signaling pathways.

### 98.3.9 $1,25(\text{OH})_2\text{D}$ Actions on Parathyroid Gland

$1,25(\text{OH})_2\text{D}$  inhibits parathyroid cell function in vitro. In particular, it decreases transcription of mRNA for preproparathyroid hormone (105), and inhibits PTH secretion and parathyroid cell proliferation (see Reference (160) for review). The expression of VDR by parathyroid cells is modulated by both extracellular calcium concentration and  $1,25(\text{OH})_2\text{D}$  (161). However,  $1,25(\text{OH})_2\text{D}$  also inhibits parathyroid cell apoptosis (162). In vitro studies have shown that  $1,25(\text{OH})_2\text{D}$  induces expression and transcription of the calcium sensing receptor (CASR) on parathyroid cells, which should make the parathyroids more sensitive to suppression of PTH release by serum calcium (163). In vivo studies of transgenic mice, in which the VDR was specifically deleted in the parathyroid glands have raised new questions about the role of VDR on regulation of PTH secretion, however (164). In these eucalcemic mice, parathyroid expression of the CASR was decreased and basal PTH levels were only moderately increased, suggesting that the VDR has a limited role in parathyroid physiology.

### 98.3.10 $1,25(\text{OH})_2\text{D}$ Actions on Calciferol Metabolism

$1,25(\text{OH})_2\text{D}$  regulates calciferol metabolism at several steps. It can increase the levels of 7,8-didehydrocholesterol in skin (165), and is a potent inhibitor of the renal  $25(\text{OH})\text{D}_3$   $1\alpha$ -hydroxylase enzyme in kidney and in many other tissues (50).  $1,25(\text{OH})_2\text{D}$  also stimulates the clearance of  $25(\text{OH})\text{D}$  and  $1\alpha, 25(\text{OH})_2\text{D}$ ; this regulated clearance is mediated by induction of 24-hydroxylation, (CYP24A1 gene) and 23-hydroxylation (166,167). Other catabolic pathways for  $1,25(\text{OH})_2\text{D}$  are likely in that the CYP24A1 knockout mouse is only hypercalcemic when fed a high-calcium diet and during pregnancy (168).

### 98.3.11 Specific Role of $24,25(\text{OH})_2\text{D}_3$

A growing body of evidence contradicts the notion that  $24,25(\text{OH})_2\text{D}$  has little or no physiological activity. It was reported that  $24,25(\text{OH})_2\text{D}$  showed unique actions on cartilage from fetal or newborn animals, not reproduced by any dosage of  $1,25(\text{OH})_2\text{D}_3$  (169,170). For example, in chicks, normal skeletal development and egg hatchability require both  $1,25(\text{OH})_2\text{D}$  and  $24,25(\text{OH})_2\text{D}$ . In addition,  $24,25(\text{OH})_2\text{D}$  appears to improve fracture repair and increase bone mass in

vitamin D-replete animals. Moreover, other recent studies have revealed that  $24,25(\text{OH})_2\text{D}$  also plays a role in endochondral ossification.  $24,25(\text{OH})_2\text{D}$  regulates the maturation of resting zone chondrocytes via phospholipase D (115,171), which produce the hormone themselves. When resting zone chondrocytes mature into growth zone chondrocytes, they become unresponsive to  $24,25(\text{OH})_2\text{D}_3$  and become responsive to  $1,25(\text{OH})_2\text{D}_3$  (115). Finally, a significant physiological role for  $24, 25(\text{OH})_2\text{D}_3$  has recently been identified in mice that are genetically deficient in  $24,25(\text{OH})_2\text{D}$  because of targeted ablation of the 24-hydroxylase gene. These mice manifest defective formation and mineralization of intramembraneous bone. This effect was previously attributed to elevated levels of  $1,25(\text{OH})_2\text{D}$  rather than low levels of  $24,25(\text{OH})_2\text{D}_3$  (135).

## 98.4 GENERAL FEATURES OF CALCIFEROL DEFICIENCY

### 98.4.1 Clinical Presentation

The general features of vitamin D deficiency (126,172,173) occur in patients with hereditary defects in calciferol metabolism or action.

The clinical features of calciferol deficiency are weakness, bone pain, bone deformity, and fracture. The mineralization defect causes its greatest effects at the epiphyses and metaphyses of the most rapidly growing bones, which develop the characteristic changes of rickets. In the first year of life, the most rapidly growing bones are the skull, ribs, and long bones. Calciferol deficiency at this time leads to widened cranial sutures, frontal bossing, posterior flattening of the skull, bulging of costochondral junctions, and enlargement of the wrists. The rib cage may be so deformed that it contributes to respiratory failure. Dental eruption is delayed, and teeth show enamel hypoplasia. Muscular weakness and hypotonia are severe and result in a protuberant abdomen. Muscular weakness may also contribute to respiratory failure. Linear growth may be adequate but the child may be unable to walk without support. Tetany is unusual as the degree of hypocalcemia is mild and its onset is slow. After age 1, deformities are most prominent in the legs because of their weightbearing function. Anemia is common.

The clinical features of calciferol-deficiency states depend principally on age of onset. Calcium and phosphate levels in fetal plasma are sustained by placental transport from maternal plasma, and this transport is probably not regulated by calciferols (174). A fetus with a hereditary abnormality in calciferol metabolism developing in a mother with normal calciferol metabolism is presumed to have normal calcium and phosphate levels in plasma and bone until birth.

In children, the mineralization defect leads to rickets, with disturbed development and maturation of diaphyses,

metaphyses, and epiphyses. The initial changes of rickets are best visualized at the growth plates of the most rapidly growing bones. In the upper limbs, the distal ulna may show the earliest effects of impaired mineralization. In the older child, the metaphyses about the knees become more useful. Early features of rickets include widening of the epiphyseal plate and a loss of definition of the provisional zone of calcification at the metaphyses. As the disease progresses, the growth plate becomes more disorganized and cupping, splaying, spur formation and stippling appear. The development of the epiphyses may be delayed or the epiphyses may appear small, osteopenic or ill defined. When the mineralization defect occurs in very early childhood, it is likely to cause genu valgum, whereas genu varum is more common when the mineralization defect occurs after the age of 2–3 years of life.

Calciferol deficiency that begins after epiphyseal fusion causes less deformity, and results in a mineralization defect termed *osteomalacia*. In the mature, remodeling skeleton, <5% of the calcium is newly deposited per year. Thus, a mineralization defect in an adult must exist for several years to be clinically manifest. The earliest symptom is bone pain, particularly low in the back. Proximal muscle weakness may be so prominent as to suggest a primary neurologic disturbance.

### 98.4.2 Pathophysiology

Virtually all the features of calciferol deficiency can be understood as direct or remote consequences of the effect of deficient calciferol on duodenal transport of calcium. Malabsorption of calcium causes hypocalcemia. Hypocalcemia and, perhaps, also the effect of deficient calciferol on the parathyroid gland (175) leads to increased secretion of PTH (i.e. secondary hyperparathyroidism). If this process continues for many months, the parathyroid glands enlarge through hypertrophy and hyperplasia. PTH acts on the proximal renal tubule to decrease reabsorption of phosphate and bicarbonate, producing hypophosphatemia and hyperchloremic metabolic acidosis. Hypophosphatemia rather than hypocalcemia appears to be the principal basis for the growth plate defect in rickets. Studies in a series of mouse models (*VDR-null*, diet-induced hypophosphatemia/hypercalcemia and hypophosphatemia secondary to mutations in the *Phex* gene) have demonstrated that normal phosphorus levels are required for growth plate maturation, and have identified phosphate-regulated apoptosis of hypertrophic chondrocytes, via activation of caspase-9, as a putative mechanism (176).

In some patients, severe vitamin D deficiency can be associated with a confusing biochemical profile, particularly when hypocalcemia is severe. In these patients, the very low serum calcium concentrations can inhibit the phosphaturic effect of PTH, resulting in PTH resistance with normal or elevated serum phosphorus levels.

These patients have elevated urinary levels of nephrogenous cyclic AMP but do not demonstrate the expected phosphaturic response (177), a condition that has been termed *pseudohypoparathyroidism type II*. In children, secondary hyperparathyroidism also causes generalized aminoaciduria. The combination of hypocalcemia and hypophosphatemia reduces the rate of mineralization of bone matrix. PTH also acts directly on bone, where it increases osteoclastic reabsorption (but the release of calcium and phosphate from bone does not fully compensate for the hypocalcemia or hypophosphatemia).

The principal goal of therapy is to provide enough calcium in extracellular fluid to allow normalization of bone mineralization and suppression of secondary hyperparathyroidism. Chronic deficiency of calciferol causes deficiency of calcium in the skeleton that can result in removal of calcium from plasma for many months during remineralization. During the early months of treatment with vitamin D or 25(OH)D<sub>3</sub>, the serum contains low calcium, high PTH, low phosphate and normal or high 25(OH)D, all of which promote synthesis of 1,25(OH)<sub>2</sub>D. The prevalence of vitamin D deficiency has increased from the 1990s to the 2000s (178,179), most likely due to a combination of factors including increasing incidence of obesity, reduced outside leisure activity and use of sunscreens.

### 98.4.3 Treatment

During the first 1–4 months of treatment, endogenous production of 1,25(OH)<sub>2</sub>D is regulated at rates greater than normal (46,180–182). A successful response to calciferol therapy is evidenced by reversal of secondary hyperparathyroidism within several weeks; that is, serum PTH and urinary cAMP fall and serum concentrations of phosphate and calcium increase and normalize. Early in treatment, there may be a transient increase in serum alkaline phosphatase, which over several months, normalizes as the bone mineralizes. In children, normal bone mass may be achieved after recovery from calciferol deficiency but in adults, bone mass may remain low (183).

### 98.4.4 Nomenclature of Vitamin D Defects

The calciferols traverse a metabolic pathway that could justify their being described as normal metabolites, vitamins (vitamin D is a dietary factor required in trace amounts in states of limited skin exposure to ultraviolet light) or hormones (1 $\alpha$ , 25(OH)<sub>2</sub>D is secreted into the bloodstream at a regulated rate by the kidney and acts on the intestine and other targets). Previous nomenclature to describe rare inborn errors of calciferol metabolism has been confusing because the terms evolved prior to elucidation of the biosynthetic pathway

**TABLE 98-2 Vitamin D-Dependent Rickets**

OMIM	25(OH)D	1,25(OH) <sub>2</sub> D	i PTH	Inheritance	Gene Defect
VDDR-1	N/I	D	I	A.R	1- $\alpha$ -hydroxylase, CYP27B1 (264700)
VDDR-2	N/I	N/I	I	A.R	Vitamin D receptor, VDR

VDDR, Vitamin D-dependent rickets.

of vitamin D activation. Several terms have included the words “deficiency” or “dependency” (e.g., pseudodeficiency, dependency, and resistance) to describe pathophysiologic states that share many features of vitamin D deficiency (i.e. calcium deficiency, secondary hyperparathyroidism, impaired skeletal mineralization), but in which no actual deficiency of vitamin D (or dietary calcium) is present. Two hereditary syndromes in which vitamin D action is impaired have been recognized. The first is classified as vitamin D-dependent rickets type 1 (VDDR-1), and is due to an inability to convert 25(OH)<sub>2</sub>D to 1,25(OH)<sub>2</sub>D. The second is type 2 vitamin D-dependent rickets (VDDR-2), and is due to generalized resistance to 1,25(OH)<sub>2</sub>D. Although the two syndromes share many clinical features, they differ in the circulating concentration of 1,25(OH)<sub>2</sub>D, the therapeutic response to 1 $\alpha$ -hydroxylated vitamin-D analogs, and obviously in the primary defect in vitamin D metabolism (Table 98-2). Recently, a novel form of inherited pseudo vitamin-D deficiency has been described (9,20), due to homozygous mutation of 25-hydroxylase (CYP2R1).

### 98.5 HEREDITARY VITAMIN D DEPENDENCY TYPE 1 (VDDR-1)-1- $\alpha$ -HYDROXYLASE DEFICIENCY

Hereditary vitamin D-dependent rickets type 1 (VDDR-1) is characterized by deficient conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D and is caused by mutations in the cytochrome P450 enzyme, 25-hydroxyvitamin D3-1  $\alpha$ -hydroxylase (CYP27B1). The complete response of the original index cases to vitamin D suggested vitamin D deficiency, but the continuing requirement for high doses of vitamin D to sustain the remission indicated a vitamin D dependency. Thus, VDDR-1 is also known as “selective and simple deficiency of 1 $\alpha$ , 25(OH)<sub>2</sub>D,” “hereditary vitamin D-pseudodeficiency type 1,” “autosomal recessive vitamin D dependency type 1 (ARVDD-1),” and “hereditary 25D, 1 $\alpha$ -hydroxylase deficiency rickets.” This disorder is a rare cause of rickets, described in approximately 100 patients (3,7,184–201). VDDR-1 occurs with unusual frequency in the French-Canadian population (186). The 1 $\alpha$ -hydroxylase gene, which is located on chromosome 12q13.3, was cloned in 1997 (26), and shortly thereafter was confirmed as the genetic defect in VDDR-1 (202).

#### 98.5.1 Clinical Features

Patients appear normal at birth but problems related to defects in mineral metabolism become obvious at 2–24 months, suggesting that the abnormality in calciferol action was present at the time of birth. Muscle weakness, irritability, tetany or convulsions, and failure to thrive are typical in the first few months of life. If diagnosed later, skeletal fractures and deformity (e.g. frontal bossing, rib cage abnormalities, and long-bone deformities) as well as growth retardation are notable. Laboratory studies reveal hypocalcemia, hypophosphatemia, and elevated serum levels of alkaline phosphatase and PTH. Plasma concentrations of 1,25(OH)<sub>2</sub>D are low or even undetectable (188,197,200,203), despite normal or even modestly increased levels of 25(OH)D (reflecting vitamin D supplementation or decreased metabolism or clearance of 25(OH)D). Plasma amino acids are normal, but generalized aminoaciduria is present. Skeletal radiographs show severe rachitic changes (see Section 98.4). Permanent teeth show enamel hypoplasia (184). If untreated, the natural history is progressive skeletal deformity and short stature. If adequately treated, healing of rickets and normal growth ensue and if treatment is started before the pubertal growth spurt, normal height can be achieved (200). At least two patients have been reported in whom CYP27B1 mutations resulted in partial 1 $\alpha$ -hydroxylase activity (198).

Reduced activity of the renal 25(OH)D<sub>3</sub> 1  $\alpha$ -hydroxylase enzyme accompanies several other hereditary or acquired disorders that are distinct from VDDR-1, and replacement of 1,25(OH)<sub>2</sub>D is an important component of the therapy for these disorders. These disorders typically affect the proximal renal tubule and include X-linked (mutation in *PHEX*), autosomal dominant (mutation in *FGF23*) and autosomal recessive (mutation in *ENPP1* or *DMP1*) hypophosphatemic rickets (204–207), as well as renal tubular acidosis (208–210), Fanconi syndrome (211–213), and tumor-induced osteomalacia (TIO). X-linked and autosomal hypophosphatemic rickets and TIO share a common pathophysiology in which a circulating phosphatonin, typically fibroblast growth factor 23 (FGF23), impairs 1 $\alpha$ -hydroxylase activity and reduces expression of *NPT2a* and *NPT2c* in the proximal renal tubule, leading to renal wasting of phosphate (214). FGF23, FRP4 (frizzled related protein 4), and MEPE (matrix extracellular phosphoglycoprotein), each possesses some or all of the properties associated

with phosphatonin, and were discovered through studies of XLH, ADHR, and TIO.

### 98.5.2 Genetics

VDDR-1 is an autosomal recessive disorder and is characterized by deficient  $1\alpha$ -hydroxylase activity. All patients reported to date, from a variety of ethnic backgrounds, have had mutations in the *CYP27B1* gene, resulting in complete or partial loss of  $1\alpha$ -hydroxylase enzyme function. Numerous different mutations have been found throughout the gene (195,201,215–221). VDDR-1 was initially mapped to chromosome 12q14 by linkage analysis in five French-Canadian families (193). The relatively isolated French-Canadian community of Saguenay in Quebec shows an unusually high prevalence of this disorder, but there appears to be allelic diversity, suggesting that more than one genetic founder must account for the disorder in these patients (220). Prediction of carrier status and early detection in newborns is possible. The  $1\alpha$ -hydroxylase enzyme is a complex system composed of three subunits (ferredoxin reductase, ferredoxin, and cytochrome P450 D1), and heterogeneity, involving mutations of different components, is therefore not surprising.

A spontaneous animal (porcine) model of VDDR-1 has been described (222), with autosomal recessive hypocalcemic rickets that is responsive to physiologic doses of  $1,25(\text{OH})_2\text{D}$  (223). Renal homogenates from homozygous animals lack  $1\alpha$ -hydroxylase and  $24$ -hydroxylase activities (224,225). Several mouse models have been developed through targeted inactivation of the  $25$ -hydroxyvitamin D-1  $\alpha$ -hydroxylase gene (*CYP27B1*) (226,227). These mice develop the typical skeletal and biochemical features of the human disorder, which are completely reversed by chronic administration of the active  $1,25(\text{OH})_2\text{D}$  metabolite. By contrast, feeding mice deficient for the *Cyp27b1* gene a rescue diet (high-calcium and lactose, 2% calcium, 1.25% phosphorus, 20% lactose) that corrects the hypocalcemia and secondary hyperparathyroidism did not entirely correct the skeletal

defects. Treated mice showed decreased bone growth as femur size remained significantly smaller than that of control mice, despite bone histology and histomorphometry confirming that rickets and osteomalacia were cured (228,229).

### 98.5.3 Management

Patients have been treated successfully with all available calciferol analogs, but use of calcitriol is the most straightforward approach to replacement therapy (188,194,230,231). Calcium supplements (elemental calcium at doses of 50 mg/kg per day to children and 1000 mg/kg per day for adults) should also be given. The specific calciferol analog used depends on several factors. The use of calcitriol has a significant theoretical advantage as  $1,25(\text{OH})_2\text{D}_3$  is the deficient hormone. Therefore, physiologic doses of calcitriol are effective. Calcitriol is available orally as a capsule or suspension, and it is generally given twice daily because of its short half-life. Treatment with vitamin D<sub>2</sub> (ergocalciferol) or vitamin D<sub>3</sub> (cholecalciferol) requires pharmacologic doses but is still less expensive than calcitriol. Ergocalciferol and cholecalciferol have significantly longer half-lives than calcitriol, which allows for once-daily dosing. However, calcitriol is the drug of choice because of its short half-life, limited distribution and fat solubility, rapid onset and offset of action, and availability in a form that may be administered intravenously. During the first 3–6 months of treatment, patients will generally require doses of calciferols that are two- to fivefold greater than the dose expected for long-term maintenance (Table 98-3), as the undermineralized skeleton requires unusually large amounts of calcium. During successful treatment with vitamin D, serum  $25(\text{OH})\text{D}$  levels will be markedly elevated (approximately 200–250 ng/mL), but the serum concentration of  $1,25(\text{OH})_2\text{D}$  may remain low or undetectable (197,203). Successful therapy maintains fractional intestinal absorption of calcium near a constant value and serum calcium in the low normal range. Because the fractional absorption of calcium

**TABLE 98-3** Calciferol Doses for Maintenance Treatment of Patients with Hereditary Defects in Calciferol Metabolism

	Dosage in VDDR-1 ( $\mu\text{g}$ per Day)	Dosage in VDDR-2 ( $\mu\text{g}$ per Day)
Vitamin D <sub>3</sub> or D <sub>2</sub>	500–3000	500–? <sup>a</sup>
$25(\text{OH})\text{D}_3$	30–200	30–? <sup>a</sup>
$1\alpha,25(\text{OH})_2\text{D}_3$	0.3–2	5–60 <sup>b</sup>
$1\alpha(\text{OH})\text{D}_3$	0.5–3	5–60 <sup>b</sup>
Dihydrotachysterol	150–1000	2000–20,000 <sup>b</sup>

Dose requirements are uncorrected for body weight and are similar in children and adults.

<sup>a</sup>Patients with milder grades of resistance to  $1\alpha,25(\text{OH})_2\text{D}$  (usually with normal hair) can respond to analogs requiring 1-hydroxylation. Maximal useful doses have not been defined. Serum  $1\alpha,25(\text{OH})_2\text{D}$  must be maintained in the range of 200–1000 pg/mL.

<sup>b</sup>Maximal doses are limited only by cost and patient acceptance; some patients have shown no response to maximal doses tested.

From Marx, S. J. Vitamin D and Other Calciferols. In *The Metabolic Basis of Inherited Disease*, 6th ed.; Scriver, C. R.; Beaudet, A. L.; Sly, W. S.; Valle, D. Eds.; McGraw Hill: New York, 1989; pp 2029.

from the gastrointestinal tract is constant in the absence of mechanisms that regulate synthesis of  $1,25(\text{OH})_2\text{D}$ , calcium homeostasis relies upon the direct actions of PTH on kidney and/or bone. Thus, levels of serum (and urine) calcium can fluctuate greatly in response to changes in the dietary calcium intake of these patients. To avoid erratic changes in serum calcium levels, these patients should receive oral calcium supplements daily to maintain a consistent dietary calcium intake. Treatment must be continued indefinitely.

## 98.6 HEREDITARY VITAMIN D-DEPENDENT RICKETS TYPE 2 (VDDR-2)

### 98.6.1 Introduction

Hereditary vitamin D-dependent rickets type 2 (VDDR-2) is an autosomal recessive disorder, in which hypocalcemia is due to true end-organ resistance to  $1,25(\text{OH})_2\text{D}$ . By analogy to VDDR-1, early reports of affected patients described responsiveness to treatment with high doses of vitamin D, and suggested that children with this disorder had a related form of vitamin D dependency. However, based on later case reports in which about half the patients with this disorder did not respond to any form of vitamin D therapy, the term VDDR-2 seems to be a misnomer. VDDR-2 is therefore more appropriately described by the terms hereditary  $1,25(\text{OH})_2\text{D}$ -resistant rickets (HVDRR) or hereditary resistance to  $1,25(\text{OH})_2\text{D}$ . VDDR-2 is a rare

syndrome, first described in 1978 (8), with over 100 individuals in at least 30 kindreds (10,192,232–236).

### 98.6.2 Clinical Features

The clinical features are almost identical to those that occur in patients with VDDR-1, but about half of patients with VDDR-2 have alopecia (234,237). Patients with VDDR-2 appear normal at birth and develop features of calciferol deficiency over the first 2–8 months of life. Alopecia, generally developing at 2–12 months, may be total or incomplete, and reflects the integrated effects of the VDR and hairless (hr) gene proteins on regulation of the mammalian hair cycle (see Section 98.3.8), as inactivating mutations in either result in alopecia (Figure 98-4). Sometimes, there is selective sparing of the eyelashes. Alopecia seems to be a marker of the more severe forms of the disease, as judged by earlier onset of hypocalcemia, more marked clinical presentation, and poor response to therapy. Other ectodermal defects have been reported in small numbers of cases and have an uncertain relation to the syndrome; these include oligodontia (238), epidermal cysts, and multiple milia (238,239).

In several cases, neonatal development was apparently normal, and hypocalcemia and/or rickets was not evident until late childhood (240) or even adulthood (241) (in the latter case, serum  $1\alpha,25(\text{OH})_2\text{D}$  was not measured, so alternative etiologies for high calciferol dose, such as non-compliance, were not excluded). In each report, the patient did not show alopecia, and each responded to high doses

**FIGURE 98-4** A 5-year-old boy with hereditary resistance to  $1,25(\text{OH})_2\text{D}$ . He was unable to sit without support at age 5. A, Despite being unresponsive to high doses of calciferols, he showed improvement 2 years later following treatment with high doses of calcium orally. B, Although the weakness and deformity improved, alopecia worsened during treatment. (From Sakati, N.; Woodhouse, N. J. Y.; Niles, N., et al. *Hereditary Resistance to 1,25-dihydroxyvitamin D: Clinical and Radiological Improvement during High-Dose Oral Calcium Therapy*. *Horm. Res.* 1986, 24, 280–287.)

of calciferols, indicating a mild variant of the syndrome. Neither showed clear features of a genetic etiology, in that there was no parental consanguinity and no affected sibling.

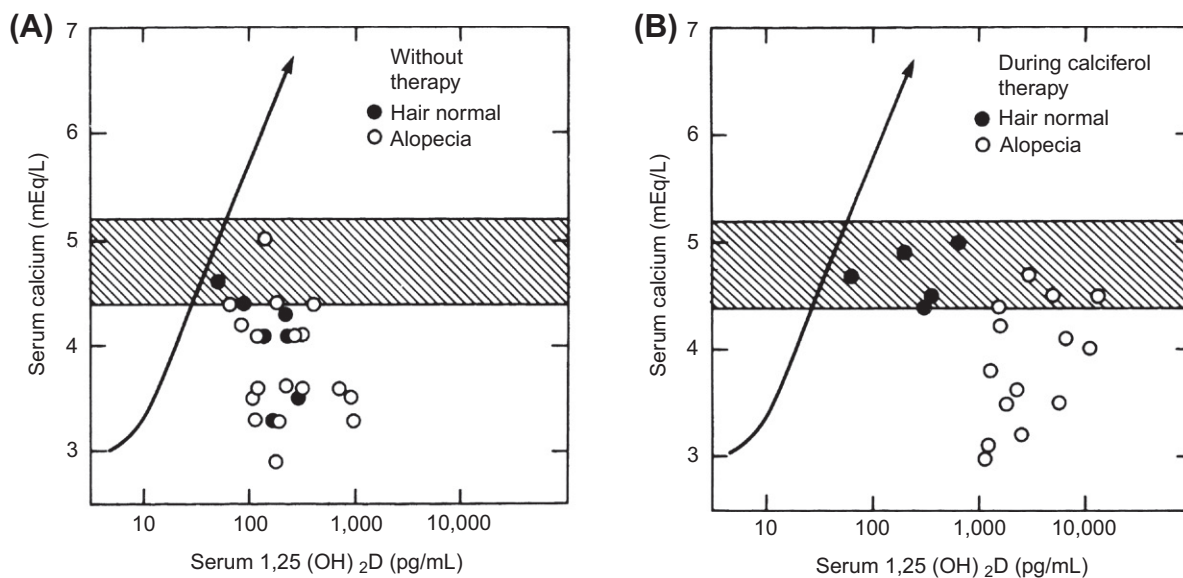

Laboratory studies show low serum concentrations of calcium and phosphorus, high serum levels of alkaline phosphatase and PTH, and generalized aminoaciduria. Unlike patients with VDDR-1, patients with VDDR-2 have elevated serum levels of  $1,25(\text{OH})_2\text{D}$ , in the range of 50–1000 pg/mL (normal in children is 30–100 pg/mL); during calciferol treatment, typical concentrations are 200–10,000 pg/mL (Figure 98-5). Basal and stimulated concentrations of insulin, thyrotropin, prolactin, growth hormone, and testosterone have been normal (242). Skeletal radiographs show severe rachitic changes. Light microscopic examination of a scalp biopsy showed normal numbers and morphology of hair follicles in a patient with total alopecia (243). Bone biopsies have shown normal or increased numbers of osteoclasts (185,244), but their resorptive activity was suggested to be impaired (185). Without therapy, this disorder leads to inanition, severe skeletal deformity, recurrent respiratory infections, and death by age 8 years.

### 98.6.3 Genetics

Inheritance of VDDR-2 is consistent with an autosomal recessive pattern. There is a striking clustering of patients in a broad region centered about the Mediterranean Sea, and this may relate to the very high consanguinity rate in patients with  $1,25(\text{OH})_2\text{D}$  receptor defects in this area (245). In addition, most cases reported from North America and Europe are descendants of families that originated from this area. Other, unrelated cases have been reported from Japan (241). The cloning and

characterization of the human VDR cDNA (72) and gene (246) facilitated molecular studies that have revealed heterogeneous mutations in the VDR in affected patients (246–252). Subsequent generation of mice deficient in VDR by gene targeting confirmed the role of the VDR in the pathogenesis of VDDR-2, and has allowed insights into not only the molecular basis for the actions of  $1,25(\text{OH})_2\text{D}_3$  in bone formation but also in development of the hair follicle (113,235,253). Remarkably, no defects in development and growth were observed before weaning, irrespective of reduced expression of vitamin D target genes. After weaning, however, mice lacking *Vdr* failed to thrive, with appearance of alopecia, hypocalcemia and infertility, and impaired bone formation. Unlike humans with VDDR-2, however, most null mutant mice have a markedly shortened lifespan, and females show uterine hypoplasia with impaired ovarian folliculogenesis. The development of alopecia and uterine hypoplasia are not observed in vitamin D-deficient animals, and thus, establish a critical role for VDR in growth, bone formation, and female reproduction in the postweaning stage (113,253). Recent work indicates that *Vdr-null* mice develop their first coat of hair normally but reinitiation of anagen after the first hair cycle is impaired (214a). Lack of *Vdr* is associated with increased expression of hairless (*Hr*), a transcriptional regulator of hair follicle cycling that appears to interact with *Vdr* to regulate hair follicle cycling (155).

Genetic studies have complemented cellular analyses of  $1\alpha$ ,  $25(\text{OH})_2\text{D}$  receptor action and DNA binding using cultured skin fibroblasts (254,255), keratinocytes (256), bone cells (94,257), and peripheral blood lymphocytes (258) from affected patients. Through a combination of several biochemical and immunological methods,

**FIGURE 98-5** Relationship between serum concentrations of calcium and  $1,25(\text{OH})_2\text{D}$ . Hatched area is normal range for calcium. Solid curve is theoretical normal relationship between calcium and  $1,25(\text{OH})_2\text{D}$ . A, Without calciferol therapy. B, During calciferol therapy. (From Marx, S. J.; Bliziotis, M. M.; Nanes, M. Analysis of the Relation between Alopecia and Resistance to  $1,25$ -Dihydroxyvitamin D. Clin. Endocrinol. 1986, 25, 373–381.)

at least six phenotypically different intracellular receptor defects have been identified:

1. Hormone binding negative. This is the most common abnormality observed, and is characterized by expression of normal amounts of receptor molecules that are unable to bind  $1\alpha, 25(\text{OH})_2\text{D}$ . The postulated mechanism, a defect in the hormone-binding domain of the VDR, has been confirmed in affected subjects from three related families, in whom a single C to A nucleotide transversion at base 970 within exon 7 converts the normal codon for tyrosine at position 292 to a premature other termination codon (250,259). This results in a truncated protein that lacks a large portion of the hormone-binding domain. Another patient was described with a point mutation leading to deletion of exon 4 (260).
2. Defect in hormone-binding capacity, in which the number of binding sites is markedly reduced (261).
3. Decreased hormone-binding affinity (233,262).
4. Deficient nuclear localization of receptors with normal or near-normal binding affinity and capacity (254,255).
5. Normal hormone binding but decreased affinity of the VDR–hormone complex for DNA sequences. Four different point mutations in exons 2 and 3 have been identified in affected members of five different kindreds with this type of defect (246,251). Each mutation caused an amino acid substitution in the region of the zinc fingers of the VDR protein, and would be predicted to impair binding of the VDR–hormone complex to DNA sequences (Figure 98-6).
6. Reduced hormone-dependent transactivation and impaired heterodimeric interaction with retinoid X receptor. Two patients have been described with mutations in the hormone-binding domain of the VDR (263).

One patient with VDDR-2 has been reported in whom no mutation in VDR could be found (264). The authors who reported this patient proposed naming the condition VDDR-3 and demonstrated an overexpression of heterogeneous nuclear ribonucleoprotein-like dominant-negative-acting hormone response element (RE)-binding protein (REBiP), a protein known to modulate steroid hormone-mediated transcription (10).

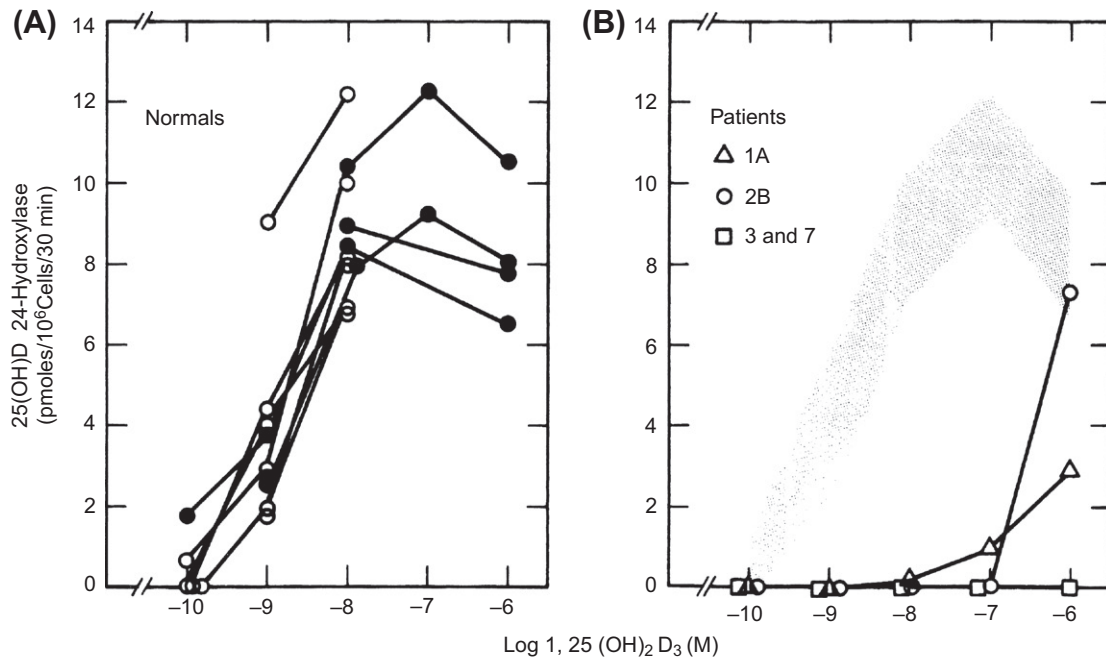

#### 98.6.4 $1,25(\text{OH})_2\text{D}$ Actions in Patients' Cells

Posttranscriptional actions of  $1,25(\text{OH})_2\text{D}$  in cells from these patients have been evaluated. The most extensively tested response to  $1,25(\text{OH})_2\text{D}$  is induction of  $25(\text{OH})\text{D}_3$  24-hydroxylase activity (265,266). In general, patients with milder disease (normal hair, calcemic response to high doses of calciferols) show inducible 24-hydroxylase with supraphysiological concentrations of  $1\alpha, 25(\text{OH})_2\text{D}_3$  (Figure 98-7), but patients with the severest disease (alopecia, no calcemic response to maximal doses of calciferols) show no 24-hydroxylase response to maximal concentrations of  $1\alpha, 25(\text{OH})_2\text{D}$ . Five of six obligate heterozygotes showed no abnormality (267); the sixth showed a 50% decrease in hormone-binding capacity and a similar decrease in maximal induction of 24-hydroxylase. Similar severe defects have been identified with analyses of inhibition of cell growth by  $1\alpha, 25(\text{OH})_2\text{D}$  (in cultured skin fibroblasts and keratinocytes (256) or in peripheral mononuclear cells (258)) and stimulation of 24-hydroxylase and of osteocalcin secretion in osteoblast-like bone cells (94).

A state resembling hereditary resistance to  $1,25(\text{OH})_2\text{D}$  is found in New World primates (marmosets and tamarinds). These animals sometimes develop

**FIGURE 98-6** Amino acid sequence and hypothetical structure of a portion of the receptor for  $1\alpha, 25(\text{OH})_2\text{D}_3$  in normals and in affected members from two kindreds with hereditary generalized resistance to  $1\alpha, 25(\text{OH})_2\text{D}_3$ . Amino acids are represented by a signal-letter code. For example, C depicts cysteine. The deduced amino acids from complementary DNA are shown as two potential zinc-finger arrays. The change in a triplet codon in exon 2 converts a glycine to aspartic acid in one kindred; the mutation in exon 3 converts an arginine to glutamine in another kindred. (Modified from Hughes, M. R.; Malloy, P. J.; Kieback, D. G. et al. Point Mutations in the Human Vitamin D Receptor Gene Associated with Hypocalcemic Rickets. *Science* 1988, 242, 1702–1705.)

**FIGURE 98-7** 25(OH)<sub>2</sub>D<sub>3</sub> 24-hydroxylase in skin fibroblasts preincubated with indicated concentrations of 1,25(OH)<sub>2</sub>D<sub>3</sub>. A, Normal subjects. B, Patients with hereditary generalized resistance to 1,25(OH)<sub>2</sub>D<sub>3</sub>. Patients 1A and 2B each showed a satisfactory calcemic response to high doses of 1,25(OH)<sub>2</sub>D<sub>3</sub>, but patients 3 and 7 showed no calcemic response. (From Gambelin, G. T.; Liberman, U. A.; Eil, C. et al. Vitamin D-Dependent Rickets Type II: Defective Induction of 25-Hydroxyvitamin D<sub>3</sub>-24-Hydroxylase by 1, 25-Dihydroxyvitamin D<sub>3</sub> in Cultured Skin Fibroblasts. *J. Clin. Invest.* 1985, 75, 954–960.)

osteomalacia in captivity and are known to have high nutritional requirements for calciferols (268). New World primates have elevated circulating concentrations of 1,25(OH)<sub>2</sub>D (230,269,270) and deficient hormone-binding affinity (271). These New World primates also exhibit hereditary resistance to several steroid hormones, including glucocorticoids, estrogens and progestins, due to overexpression of two types of proteins that modify hormone-directed transactivation and metabolism, heterogeneous nuclear ribonucleoproteins and heat shock protein-70 heterogeneous (272,273).

### 98.6.5 Treatment

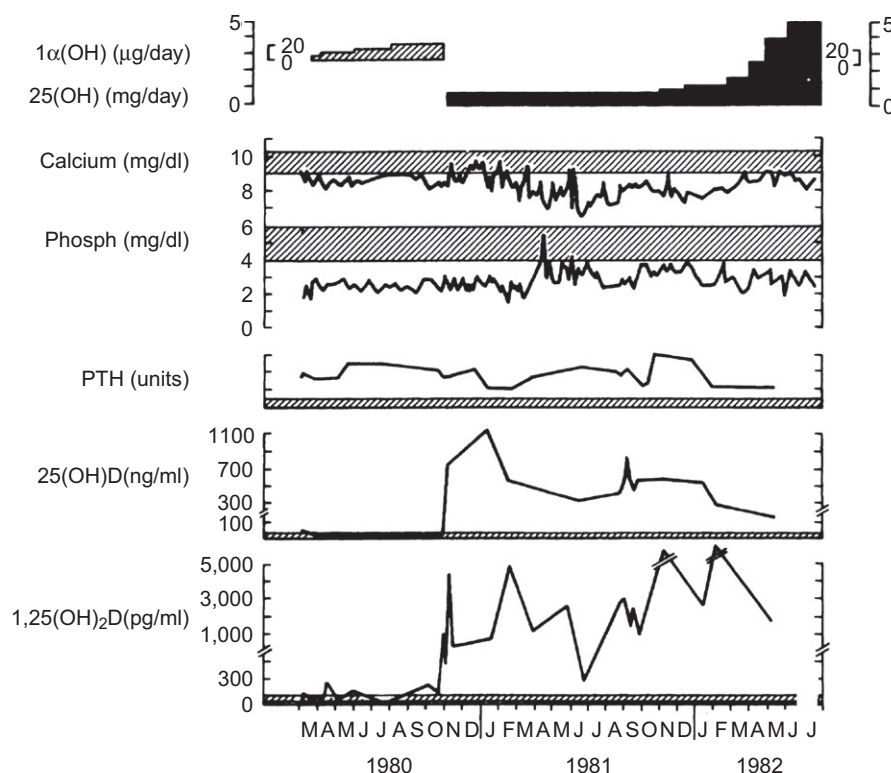

Many cases show complete remission while receiving extraordinarily high doses of calciferols (274) (Table 98-2). Alopecia is one simple predictor of potential for response to therapy (275). Virtually all cases with normal hair can sustain remission when given high doses of analog not requiring 1-hydroxylation. Among cases with alopecia, approximately half are resistant to the highest doses of calciferols achievable; the other half have shown a satisfactory calcemic response, but the dose requirement is typically 10 times higher than in those with normal hair (Figure 98-8). Maintenance treatment is based upon four considerations: (1) some patients can be treated with calciferols (vitamin D<sub>3</sub>, vitamin D<sub>2</sub>) that provide substrate for production of very high serum levels of 1α, 25(OH)<sub>2</sub>D; (2) others may respond only to very high doses of analogs (1α, 25(OH)<sub>2</sub>D<sub>3</sub>, 1α-(OH)D<sub>3</sub>, dihydrotachysterol) that do not require

1α-hydroxylation by the kidney; (3) a minority may not respond to maximal doses of any calciferols; and (4) the role of calcium supplements is different in each of the previous three groups (see discussion below).

Several patients have shown remissions while receiving high doses of vitamin D<sub>2</sub> or 25(OH)<sub>2</sub>D<sub>3</sub> (8,234). In these cases, tissue resistance is only moderate; sufficient 1α, 25(OH)<sub>2</sub>D is produced endogenously from high concentrations of substrate in response to elevated circulating PTH. In this group, calcium supplements may have little or no role as serum concentrations of PTH and 1α, 25(OH)<sub>2</sub>D can compensate for fluctuations in calcium availability.

Patients unable to produce sufficient 1α, 25(OH)<sub>2</sub>D endogenously (because of a requirement for particularly high 1α, 25(OH)<sub>2</sub>D concentrations) may still respond to extraordinarily high doses of analogs that do not require 1α-hydroxylation (i.e. 1,25(OH)<sub>2</sub>D<sub>3</sub>, 1α(OH)D<sub>3</sub>, dihydrotachysterol). Patients in this group requiring therapy that bypasses 1α-hydroxylation should receive fixed calcium supplements (1000 mg per 24 h elemental calcium), for the same reasons as patients with hereditary selective deficiency of 1α, 25(OH)<sub>2</sub>D.

Some patients show no response to maximal doses of any calciferol (Figure 98-8) (185,261,276). Patients with inadequate responses to calciferols can obtain substantial benefit from intravenous infusions of calcium (244,261,277); high-calcium doses (1000mg elemental calcium per 24 h infused over 12 h) can be tolerated even by young children with this disorder. Because normal positive calcium balance during childhood growth is approximately 300mg/24h and deficits prior to

**FIGURE 98-8** Absent calcemic response during a long therapeutic trial with calciferols. Calciferol therapy is in upper panel:  $1\alpha(\text{OH})$  refers to  $1\alpha(\text{OH})\text{D}_3$  or  $1,25(\text{OH})_2\text{D}_3$  and  $25(\text{OH})$  refers to  $25(\text{OH})\text{D}_3$ . Hatched zones indicate normal ranges. Not only is hypocalcemia persistent but also secondary hyperparathyroidism persists (high parathyroid hormone and low phosphate), and very high serum levels of  $1\alpha,25(\text{OH})_2\text{D}$  are documented. (From Marx, S. J.; Liberman, U. A.; Eil, C. et al. *Hereditary Resistance to 1,25-Dihydroxyvitamin D*. *Rec. Prog. Horm. Res.* 1984, 40, 589–615.)

treatment are large, such infusions must be given repeatedly over many months to accomplish significant results. This form of therapy requires methods similar to those used in hyperalimentation programs. Another way to increase calcium input to the bloodstream is to increase net absorption independent of calciferols (239). Unfortunately, the upper limit of tolerance to calcium by mouth is around 6000 mg per day and requires great cooperation; in the absence of calciferol bioeffect, the net calcium retention is approximately 10%. The requirement for intravenous or very high doses of oral calcium confirms the importance of  $1,25(\text{OH})_2\text{D}$ -dependent active transport of calcium in the upper intestine for physiological absorption of calcium.

As in the calciferol-deficiency states, total body calcium requirements are highest at the onset of treatment. Thus, the doses of calcium, the doses of calciferols, and the type of approach judged necessary to initiate therapy (for example intravenous calcium) may not prove to be the same as those required for maintenance therapy.

### 98.7 STATES RESEMBLING HEREDITARY GENERALIZED RESISTANCE TO $1,25(\text{OH})_2\text{D}$

There are multiple forms of hereditary or acquired rickets or osteomalacia in which calciferol metabolism is normal or, if abnormal, only as an appropriate

response to a primary disturbance in mineral flux. Rickets or osteomalacia with high circulating  $1,25(\text{OH})_2\text{D}$  is found in generalized resistance to  $1,25(\text{OH})_2\text{D}$  and in two additional states (calcium deficiency or phosphate deficiency).

#### 98.7.1 Calcium Deficiency

Rickets due to dietary calcium deficiency is unusual under normal dietary conditions, but has been described in infants fed with a low calcium soy-based formula as the main source of nutrition, as well as in children with low dietary calcium intakes both in the developing world (92,278–281) and more recently in the United States (282). The resulting calcipenia leads to secondary hyperparathyroidism, increased urinary phosphate excretion, and subsequent hypophosphatemia. Of course, calcium repletion cures all abnormalities. Osteopetrosis (marble bone disease) is caused by several types of defect (usually hereditary) in osteoclast function. Both in humans and in animal models of this disease, serum  $1,25(\text{OH})_2\text{D}$  is increased and subtle histologic changes of osteomalacia have been noted (283), particularly in patients with “osteopetrorickets” due to mutations in the *TCIRG1* gene that encodes a subunit of the vacuolar proton pump specifically expressed in both osteoclasts and gastric parietal cells (284). Mice deficient in *Tcirg1* have low gastric acid levels (hypochlorhydria) and mild

hypocalcemia, which suggests that gastric acid levels, rather than solely affecting osteoclast activity, help determine proper serum calcium levels, and that osteopetrorickets and osteopetrosis are distinct phenotypes. At least one patient has been treated with a low-calcium diet, plus high doses of  $1,25(\text{OH})_2\text{D}_3$ , with apparent improvement in osteoclast function (285). Other cases of osteopetrosis have not responded to similar treatment, and at least one cellular defect (carbonic anhydrase II deficiency) unlikely to be overcome by  $1,25(\text{OH})_2\text{D}_3$  has been discovered (286).

### 98.7.2 Phosphate Deficiency

Severe deficiency of phosphate can cause rickets with high  $1,25(\text{OH})_2\text{D}$ . In hereditary hypophosphatemic rickets with hypercalciuria, homozygous mutations of *SLC34AC* leads to loss of function of the NaPiIIc sodium-phosphate cotransporter, and the renal loss of phosphate causes osteomalacia and activation of the renal  $1\alpha$ -hydroxylase (287a,175a,288,289). High  $1,25(\text{OH})_2\text{D}$  causes absorptive hypercalciuria; parathyroid function is suppressed, unlike in hereditary generalized resistance to  $1,25(\text{OH})_2\text{D}$ .

Survivors of extreme prematurity can pass through a phase when their growing bones (deprived of the placental pump) are severely deficient in both calcium and phosphate, producing neonatal rickets with high serum  $1,25(\text{OH})_2\text{D}$  (290,291). In this group, immaturity of intestinal responsiveness to  $1,25(\text{OH})_2\text{D}$  may contribute to the disturbance (85).

### 98.7.3 Deficient Bone Mineralization with Normal Calcium and Phosphate in Serum

There are several causes of deficient bone mineralization with otherwise normal calcium and phosphate fluxes. These include fibrogenesis imperfecta ossium, hypophosphatasia (292), the chondrodysplasias (which can disturb epiphyseal function), and skeletal accumulation of aluminum, bisphosphonates, or fluoride (172). Because PTH is not high or phosphate is not low in serum,  $1\alpha,25(\text{OH})_2\text{D}$  is normal in serum.

## 98.8 OTHER HEREDITARY DEFECTS IN CALCIFEROL METABOLISM OR ACTION

### 98.8.1 Calciferol-Deficiency States

Although antigenic variation in vitamin D-binding protein (Gc) is common, no differences in its function for calciferol transport have been identified in humans (293). However, in the chicken, this protein shows 10-fold higher affinity for vitamin D3 metabolites than for vitamin D2 metabolites, and this seems to account

for a higher requirement for vitamin D2 than D3 in this species (287).

Congenital rickets due to genetic defects in 25-hydroxylase deficiency has been reported as an unusual cause of vitamin D deficiency (20).

Deficient 24-hydroxylation of  $25(\text{OH})\text{D}$  was suggested in another patient with hereditary generalized resistance to  $1\alpha,25(\text{OH})_2\text{D}$  (238). That patient showed low concentrations of  $24,25(\text{OH})_2\text{D}$  and showed partial remission of resistance when given  $24,25(\text{OH})_2\text{D}_3$ . These observations remain unexplained, but a persistent abnormality in DNA binding of the  $1\alpha,25(\text{OH})_2\text{D}$  receptors has been documented in cells cultured from this patient (294), suggesting that the receptor defect is her primary problem. Decreased production of  $24,25(\text{OH})_2\text{D}$  could be secondary to the abnormality in  $1,25(\text{OH})_2\text{D}$  action, as one of its actions is induction of  $25(\text{OH})\text{D}_3$  24-hydroxylase.

### 98.8.2 Calciferol Excess States: Idiopathic Infantile Hypercalcemia

Idiopathic infantile hypercalcemia was recognized as a syndrome in the 1950s (295). Most patients present within the first year of life with failure to thrive, dehydration and vomiting, in some accompanied by nephrocalcinosis. PTH levels are suppressed. Since its description, there has been speculation that the cause was an increased sensitivity to vitamin D present in infant formula (296). Recently, through a candidate screening approach, several different inactivating mutations in *CYP24A1* were reported in six patients (from four families in Germany) with autosomal recessively inherited idiopathic infantile hypercalcemia (297). In these patients, four presented ages between 6 and 11 months with failure to thrive and nephrocalcinosis and two with more mild hypercalcemia were asymptomatic, diagnosed by family screening. Interestingly, serum  $1,25(\text{OH})_2\text{D}$  was only frankly elevated in one of these patients. In addition, in this report (297), four infants (5 weeks to 7 months old) with suspected vitamin D intoxication were also described, with similar mutations to those found in the familial cases. Mutations in *CYP24A1* can rarely be seen as a cause of hypercalcemia in adults as well. One of the authors (EAS) and her group found a *CYP24A1* mutation in a 45-year-old man with hypercalcemia (homozygous E143del) who presented at age 19 with hypercalcemia and nephrolithiasis (298). Unlike the infantile cases, in the adult with hypercalcemia and *CYP24A1* mutation, serum  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  were consistently and frankly elevated.

### 98.8.3 Calciferol Sensitivity States: Williams Syndrome

Three groups (299–301) described patients with a constellation of unusual features, including infantile hypercalcemia, prenatal and postnatal growth deficiency, elfin

fancies, mental retardation and supravalvular aortic stenosis, which now is called Williams syndrome (see Chapter 46). It is also called Williams–Beuren syndrome.

### 98.8.4 Clinical Features

The characteristic dysmorphology includes the following: wide slack mouth, malocclusion, prominent upper lip, underdeveloped mandible, depressed nasal bridge, hypertelorism, epicanthic folds, low-set ears, increased bone density, craniostenosis, and osteosclerosis, especially at the base of the skull. Neurologic manifestations include hypotonia, hyperreflexia, and motor retardation. Children are unusually friendly and have been described as having “cocktail party” personalities. Renal involvement is common in Williams syndrome, including nephrocalcinosis and anatomic defects. A variety of clinical manifestations can occur including renovascular hypertension, proteinuria, and an elevated plasma creatinine concentration.

Cardiovascular abnormalities involve local or diffuse stenosis of the medium-sized or large-sized arteries, most commonly in the ascending aorta above the aortic valves (i.e. supravalvular aortic stenosis) or in the pulmonary arteries. Nonetheless, stenosis of the descending aorta, intracranial arteries, and renal arteries has been reported. Overall, unexpected death is rare but is 25-fold to 100-fold higher than in age-matched control subjects. Factors implicated in sudden death have included supravalvular aortic stenosis, severe pulmonary stenosis, and myocardial ischemia secondary to either coronary insufficiency or biventricular outflow tract obstruction with ventricular hypertrophy. Coronary insufficiency appears most likely because of stenosis that results from intimal fibrosis and muscular hypertrophy. Stroke and hypertension occur at younger-than-expected ages. Cases showing portions of the phenotype have sometimes been collected within this syndrome without implying identical pathophysiology for all cases (302). Early studies showed elevated serum and urine levels of calcium during the first year of life and a tendency to develop nephrocalcinosis. Hypercalcemia rarely persists after the first year of life, but persistent hypercalciuria is not uncommon. Although many reports of children with Williams syndrome have failed to document a high frequency of hypercalcemia, in a report of 50 cases from Greece, three had hypercalcemia (303). Serum 25(OH)D and 24,25(OH)<sub>2</sub>D are normal (304), but circulating levels of 25(OH)D show excessive increases after administration of vitamin D (305). Serum 1 $\alpha$ ,25(OH)<sub>2</sub>D levels have been reported to be elevated (306), or suppressed (304,307,308), suggesting more than one mechanism for the hypercalcemia (309).

### 98.8.5 Genetics

Most cases appear to be sporadic, but some have had affected siblings (310) and autosomal-dominant-like pedigree can occur (311). Insights into the molecular basis

for Williams syndrome came from the study of patients with isolated supravalvular aortic stenosis, a distinct autosomal-dominant disorder caused by mutations in the elastin (*ELN*) gene (312). Analysis of patients in whom supravalvular aortic stenosis occurred as part of the Williams syndrome revealed hemizygous chromosomal deletions at chromosome band 7q11.23 (313), which includes the elastin gene (*ELN*). Most deletions are not detected through standard karyotyping but rather through CGH microarray or fluorescent in situ hybridization (FISH) for a 1.5-Mb deletion. The size of the deletion can vary. Williams syndrome is not solely caused by elastin haploinsufficiency; the deletion involves a region that spans more than 25 genes and, hence, is considered a contiguous gene deletion syndrome. The cardiovascular findings, part of the connective tissue pathology, and facial dysmorphology are attributed to the elastin gene haploinsufficiency, while the other features of Williams syndrome are likely due to loss of adjacent genes in the region of chromosome 7q11.2 (314,315). Elastin arteriopathy is generalized; thus, virtually any artery may be affected.

Williams syndrome has also been associated with other chromosomal abnormalities including an interstitial deletion of chromosome 6(q22.2q23) (316), a terminal deletion of chromosome 4[46,XX,del(4)(q33)] (317), as well as chromosomal translocations (318,319). However, the definitive basis remains unknown (315). In most cases, fluorescent in situ hybridization (FISH) using a probe for *ELN* is diagnostic (320,321).

The offspring of rabbits with vitamin D intoxication show similar skeletal features (mandibular hypoplasia and characteristic dental abnormalities) (322). It is uncertain, at this point, whether the pathogenesis of the Williams syndrome involves a defect in calciferol metabolism or not.

### 98.8.6 Management

The most important aspect of the treatment of hypercalcemia is a low-calcium diet with elimination of vitamin D. In newborns and infants, the daily calcium intake should be kept below 100 mg and preferably as low as 25–35 mg; Calcilo XD is a suitable low-calcium infant formula that lacks vitamin D. It is necessary not only to eliminate vitamin D intake but also to protect the infant from exposure to direct sunlight. It has been recommended that the low-calcium, low-vitamin-D diet be maintained for at least 9 months after the serum calcium has become normal. Corticosteroids may be a useful adjunct in the acute stage to induce rapid lowering of the plasma calcium level and can usually be discontinued after a few days when the diet has produced its effects. In general, hypercalcemia resolves without specific treatment by the end of the first year of life. Intravenous bisphosphonates can also be used to treat the hypercalcemia (323). Otherwise, there is no specific treatment available other than specific treatment for skeletal deformities.

### Biographies

**Dr Michael A Levine** is the Chief of Endocrinology and Diabetes and Director of the Center for Bone Health at The Children's Hospital of Philadelphia. Dr Levine holds the Lester Baker Endowed Chair and is a Professor of Pediatrics and Medicine at the University of Pennsylvania Perelman School of Medicine. Dr Levine's research focuses on the genetic basis of disorders of bone and mineral metabolism and complements his clinical expertise in endocrine diseases that affect bone and mineral metabolism. His approach is to apply molecular and genetic tools to analyze the basis of altered hormone action, particularly in G protein-coupled signal transduction systems that affect growth and development. He has identified the molecular basis of several inherited disorders of mineral metabolism, including familial hypoparathyroidism, pseudohypoparathyroidism, and the McCune Albright syndrome. His research interests now extend to the molecular events that control embryological development of the parathyroid glands and genetic modifiers of vitamin D action.

**Dr Streeten** is an endocrinologist, clinical geneticist and Associate Professor of Medicine and Pediatrics at the University of Maryland School of Medicine. She has active practices of both metabolic bone disease and clinical genetics and teaches medical students, residents and fellows. Much of Dr Streeten's research has focused on the study of bone health in the Old Order Amish, including participating in meta-analyses of genomewide association studies of bone density and bone geometry. She has also been studying osteoporosis–pseudoglioma syndrome since 1998, focusing on evaluating bone quality (with peripheral CT) and developing new treatments to reduce fracture risk. Other research interests include hypercalcemia related to *CYP24A1* mutation and the effects of vitamin D repletion on cardiovascular risk factors.

### 99.1 INTRODUCTION

The inherited porphyrias are a diverse group of inborn errors of metabolism, with each resulting from the deficient activity of a specific enzyme in the heme biosynthetic pathway (Tables 99-1 and 99-2). The resultant accumulation of porphyrin precursors and/or porphyrins causes the major clinical manifestations, neurologic symptoms, and/or cutaneous photosensitivity. These seven disorders are classified metabolically as hepatic or erythropoietic, depending on the primary source of their accumulated heme biosynthetic intermediates. They also are classified clinically as acute or cutaneous. Of the five hepatic porphyrias, four are characterized by life-threatening acute attacks of neurologic manifestations that occur in association with excess amounts of the porphyrin precursors, 5-aminolevulinic acid (ALA), and porphobilinogen (PBG), and they are classified as acute porphyrias. Three porphyrias have primarily cutaneous manifestations, including the two erythropoietic porphyrias and porphyria cutanea tarda (PCT). Two other hepatic porphyrias, hereditary coproporphyria (HCP) and variegate porphyria (VP), may cause acute neurologic attacks and cutaneous manifestations. The skin damage results from photoactivation of the accumulated porphyrins by long-wave ultraviolet (UV) light.

From a genetic point of view, the porphyrias are unique as five of the seven disorders are autosomal dominant enzymopathies. Of note, only a minority of heterozygotes becomes symptomatic. The onset and severity of the hepatic porphyrias are greatly influenced by environmental and metabolic factors, such as hormones, drugs, and nutrition. In addition, modifying genes presumably play an important role in the clinical expression of these disorders.

Here, we describe the clinical, metabolic, and genetic features of the seven porphyrias; mutations in the first enzyme in the heme biosynthetic pathway cause X-linked sideroblastic anemia (1). Optimal methods for their diagnosis and treatment are presented, and the current understanding of the genetic basis and disease pathogenesis in these acute and cutaneous disorders are discussed. Recent reviews on the inherited porphyrias are available (1–5). For lists of mutations causing each porphyria, please see the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6). Informative and up-to-date Web sites are sponsored by the American Porphyria Foundation ([www.porphyrifoundation.com](http://www.porphyrifoundation.com)) and the European Porphyria Initiative ([www.porphyrria-europe.org](http://www.porphyrria-europe.org)).

### 99.2 THE HEME BIOSYNTHETIC PATHWAY

#### 99.2.1 The Heme Biosynthetic Enzymes

The heme biosynthetic pathway is shown in Figure 99-1 and Table 99-1. Nine nuclear heme biosynthetic genes, including separate genes for the housekeeping and erythroid-specific isozymes of ALA-synthase, encode the enzymes that catalyze the eight steps in the conversion of glycine and succinyl-CoA to heme (1). The first and the last three enzymes are in the mitochondrion, and the other four function in the cytosol. The characteristics of the genes, their respective enzymes, and their chromosomal locations are summarized in Table 99-1. The heme biosynthetic pathway is responsible for the production of heme for hemoproteins, including the superfamily of cytochrome P450 enzymes, which are most abundant in the liver, and hemoglobin in erythrocytes.

**TABLE 99-1 Human Heme Biosynthesis Enzymes and Genes<sup>a</sup>**

Enzyme	Gene Symbol	Chromosomal Location	cDNA (bp)	Protein (aa)	Gene	
					Size (kb)	Exons <sup>b</sup>
5-Aminolevulinate synthase: (ALA-synthase)						
Housekeeping	ALAS1	3p21.1	2,199	640	17	11

<sup>b</sup>Number of exons and (in parentheses) those encoding separate housekeeping and erythroid-specific forms.

Different regulatory controls have evolved for hepatic and erythroid-specific heme synthesis, including negative feedback repression by heme in the liver, and separate erythroid-specific genes or promoters in the first four genes in the pathway (Figure 99-2). Each of the enzymatic steps in the pathway is briefly described in this chapter.

**99.2.1.1 5-Aminolevulinate Synthase.** The first enzyme in the pathway, 5-aminolevulinate synthase (ALA-synthase; also known as D-aminolevulinate synthase; E.C. 2.3.1.37), catalyzes the condensation of glycine (activated by pyridoxal phosphate) and succinyl coenzyme A to form ALA. Distinct human housekeeping and erythroid-specific ALA-synthase isozymes are encoded by separate genes: the ~17-kb housekeeping gene (ALAS1), located at chromosome 3p21.1, is expressed in all tissues, while the ~22-kb erythroid-specific gene (ALAS2), located at chromosome Xp11.21, is expressed only in erythroid cells to supply the large amounts of heme required for hemoglobin (see Figure 99-2). These findings provide a basis for the tissue-specific regulation of this pathway (for a review see Reference (1)). Of note, expression of the housekeeping gene ALAS1 in the liver is under negative feedback repression by the cellular heme concentration and functions to modulate the supply of heme for the hepatic cytochrome P450 enzymes and other hepatic hemoproteins (7). In acute porphyrias, the depletion of hepatic heme by various drugs, hormones, and glucose restriction, the increased synthesis of the housekeeping ALAS1 isozyme, and the generation of

the large amount of the porphyrin precursors, ALA and PBG, are the biochemical hallmarks of acute neurologic attacks (2).

Mutations in the X-linked ALAS2 gene and the resultant deficient activity of the erythroid-specific isozyme cause X-linked sideroblastic anemia (1,8). Over 35 mutations in the erythroid-specific ALA-synthase gene causing X-linked sideroblastic anemia are listed in the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6). Except for a mutation in the promoter region of the ALAS2 gene (9) and one nonsense mutation, all of the reported lesions have been missense mutations in the ALAS2 catalytic core encoded by exons 5 to 11, with the majority occurring in exons 5 and 9. Most mutations were pyridoxine responsive in vivo and when expressed in *Escherichia coli*. Molecular modeling of the ALAS2 isozyme, based on the crystal structure of a bacterial ALA-synthase, suggested the molecular basis for the pyridoxine responsiveness of certain mutations (10). Recently, gain of function mutations in exon 11 of ALAS2 that increase its activity have been shown to cause an X-linked form of erythropoietic protoporphyria (EPP), known as X-linked protoporphyria (XLP). To date, only two gain of function mutations in ALAS2 have been described. No deficiencies of the ALAS1 isozyme have been described; presumably, the enzymatic deficiency would be lethal.

**99.2.1.2 5-Aminolevulinic Acid Dehydratase.** The second enzyme in the pathway is 5-aminolevulinic acid dehydratase (ALA-dehydratase; also known as PBG synthase; E.C. 4.2.1.24). This enzyme catalyzes the

**TABLE 99-2 Classification of the Human Porphyrrias including Major Clinical and Biochemical Features**

						Biochemical Findings <sup>a</sup>
	Symptomatology Porphyria	Enzyme	H or E	Principal Inheritance	Deficient NV or CP	Classification Erythrocyte

H, hepatic; E, erythropoietic; AR, autosomal recessive; AD, autosomal dominant; Type I isomers: ALA = 5-aminolevulinic acid; PBG = porphyrinogen; NV, neurovisceral; CP, cutaneous.

<sup>a</sup>Increases that may be important for diagnosis.

<sup>b</sup>These porphyrias also have erythropoietic features including increased erythrocyte porphyrins.

<sup>c</sup>Inherited deficiency of UROD is partially responsible for familial (Type II) PCT.

<sup>d</sup>Polymorphism in intron 3 of wild-type allele affects level of enzyme activity and clinical expression.

**FIGURE 99-1** The human heme biosynthetic pathway. Ac, acetyl; Pr, propionyl.

condensation of two molecules of ALA to form the cyclic pyrrole, PBG (see Figure 99-1). Human ALA-dehydratase is composed of eight identical 31-kDa subunits and eight atoms of zinc, which are required for both enzyme stability and catalytic activity. The zinc atoms are bound to each subunit by a typical zinc finger domain consisting of four cysteine and two histidine residues (1). The zinc atoms protect essential sulfhydryl groups in the enzyme and can be displaced by lead or other heavy metals. In fact, the measurement of erythrocyte ALA-dehydratase activity is a highly sensitive index of lead exposure.

The 16-kb human ALA-dehydratase gene encodes housekeeping and erythroid-specific transcripts by alternative splicing (11); see Figure 99-2. Both transcripts encode the same amino acid sequence, as translation begins in exon 2. The housekeeping promoter region is upstream of exon 1A, while the erythroid-specific promoter is upstream of exon 1B. Mutations in the ALA-dehydratase gene result in the deficiency of ALA-dehydratase, causing a rare, recessively inherited acute hepatic porphyria, ALA-dehydratase-deficient porphyria (ADP) (6,12,13). Only six cases of ADP with 13 different ALA-dehydratase mutations have been reported ([www.hgmd.org](http://www.hgmd.org)) (6,14).

Of note, there are two common alleles at the ALA-dehydratase locus, ALAD1 and ALAD2, which are responsible for three electrophoretically distinguishable enzyme forms designated 1-1, 1-2, and 2-2. The frequencies of the corresponding phenotypes in white populations are about 80%, 18%, and 1%, respectively,

giving gene frequencies of 0.9 and 0.1 for the ALAD1 and ALAD2 alleles, respectively. Gene frequency of the ALAD2 allele is lower in Hispanics, Asians, and African-Americans (15), and in a Liberian population, the ALAD2 allele was not detected. The ALAD2 allele has normal ALA-dehydratase activity but may bind zinc more effectively. Several epidemiologic studies have demonstrated an association between the ALAD2 allele and high lead levels (16–20). Although blood and serum lead levels were 5%–10% greater in individuals with the ALAD2 allele than in individuals with the other alleles, bone lead was not increased (17).

**99.2.1.3 Hydroxymethylbilane Synthase.** Hydroxymethylbilane synthase (HMB-synthase; formerly known as PBG-deaminase or uroporphyrinogen I synthase; E.C. 4.3.1.8), the third enzyme in the pathway, catalyzes the head-to-tail condensation of four molecules of PBG by a series of deaminations to form the linear tetrapyrrole, hydroxymethylbilane (HMB) (see Figure 99-1). HMB can cyclize nonenzymatically to form uroporphyrinogen I, a nonphysiological and phototoxic compound. Because HMB-synthase activity is almost as low as ALA-synthase activity in the liver, it may become rate-limiting when the enzyme is partially deficient. The ~10-kb human HMB-synthase gene encodes erythroid-specific and housekeeping isozymes by alternative splicing (see Figure 99-2). The housekeeping and erythroid isozymes are monomeric proteins of 361 and 344 amino acid residues, respectively. The housekeeping promoter functions in all cell types, whereas the

a-helices and a discrete hydrophobic core. Because the human and *E. coli* HMB-synthase amino acid sequences have about 35% homology and greater than 70% similarity, it was possible to infer the structure–function relationships for certain human HMB-synthase mutations from the bacterial enzyme (24,25).

**99.2.1.4 Uroporphyrinogen III Synthase.** Uroporphyrinogen III synthase (URO-synthase; E.C. 4.2.1.75) catalyzes the rearrangement of HMB by inversion of the pyrrole D ring and ring closure to form the asymmetric uroporphyrinogen type III isomer (see Figure 99-1). In the absence of URO-synthase, HMB nonenzymatically cyclizes to form the uroporphyrinogen I isomer. This nonphysiologic compound can be metabolized to coproporphyrinogen I, but further metabolism cannot proceed as the next enzyme, coproporphyrinogen oxidase, is stereospecific for the III isomer.

The ~34-kb human URO-synthase gene has alternative promoters that generate housekeeping and erythroid-specific transcripts, which encode the same 265 amino acid polypeptide (see Figure 99-2) (26). The enzyme is active as a 29.5-kDa monomer. The human enzyme has been crystallized at a resolution of 1.85 Å (27). The protein folds into two alpha/beta domains connected by a beta-ladder, with the active site between the domains.

Mutations in the URO-synthase gene results in deficient but not absent, URO-synthase enzyme activity, causing congenital erythropoietic porphyria (CEP), an autosomal recessive erythropoietic porphyria (6,28). Over 35 URO-synthase mutations are listed in the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6).

**99.2.1.5 Uroporphyrinogen Decarboxylase.** Uroporphyrinogen-decarboxylase (E.C. 4.1.1.37), the fifth enzyme in the pathway, catalyzes the sequential removal of the four carboxyl groups from the acetic-acid side chains of uroporphyrinogen III (clockwise, starting with ring D) to form the four methyl groups of coproporphyrinogen III, a tetracarboxyl porphyrinogen (see Figure 99-1). The enzyme has no coenzyme or metal requirements, and iron does not appear to directly affect URO-decarboxylase activity in vitro.

The ~3-kb human URO-decarboxylase gene has a single-mRNA species, which expresses a 367-residue polypeptide in all tissues, where it is active as a homodimer (29,30). Recombinant human URO-decarboxylase has been crystallized at 1.60-Å resolution, and its reaction mechanism has been studied (30–33).

This enzyme is deficient in the liver in PCT, the most common porphyria. The majority (~80%) of PCT patients have no URO-decarboxylase mutations and are termed type I if the disease is sporadic or type III, if (rarely) more than one family member is affected. Heterozygous mutations and half-normal enzyme activities are found in all tissues (e.g. erythrocytes) in familial (type II) PCT (~20% of all PCT patients). In overt PCT of all types, hepatic URO-decarboxylase activity is always

reduced by additional factors to well below 50% of normal, which is consistent with an acquired tissue-specific inhibition of hepatic URO-decarboxylase. Hepatoerythropoietic porphyria (HEP) is the homozygous form of familial (type II) PCT and, generally, has a more severe phenotype (1,34). Over 100 URO-decarboxylase mutations identified in PCT and HEP are listed in the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6).

**99.2.1.6 Coproporphyrinogen Oxidase.** The sixth enzyme in the pathway, coproporphyrinogen oxidase (COPRO-oxidase; E.C. 1.3.3.3), catalyzes the decarboxylation of two of the four propionic acid groups of coproporphyrinogen III (on rings A and B) to form the two vinyl groups of protoporphyrinogen IX, a dicarboxyl porphyrinogen (see Figure 99-1). COPRO-oxidase is located between the mitochondrial inner and outer membranes, requires molecular oxygen for its activity, and contains no metals (1,35). An intermediate in the two-step decarboxylation is a 3-carboxyl porphyrinogen (termed harderoporphyrinogen, because this porphyrin in its oxidized form (harderoporphyrin) was first isolated from the rodent harderian gland). Coproporphyrinogen I, which is formed by decarboxylation of uroporphyrinogen I, is not a substrate for this enzyme and therefore is not metabolized to heme.

The ~14-kb human COPRO-oxidase gene encodes a single transcript, which expresses a 474-residue polypeptide including an N-terminal mitochondrial, targeting signal peptide of 120 residues (36–38). Human COPRO-oxidase has been crystallized to a resolution of 1.58 Å (39). Studies of the crystal structure confirmed that COPRO-oxidase functions as a dimer and identified the residues in the enzyme's active site (39).

Mutations in the COPRO-oxidase gene result in deficient enzymatic activity, causing HCP, an autosomal dominant disorder (40). Over 40 COPRO-oxidase mutations are listed in the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6). Mutation K404E in the COPRO-oxidase gene, when present in either the homozygous or compound heterozygous states, causes a biochemical variant, termed harderoporphyrin (39,41). Cases of homozygous dominant HCP have also been described (6,42,43).

**99.2.1.7 Protoporphyrinogen Oxidase.** The seventh enzyme in the pathway, protoporphyrinogen oxidase (PROTO-oxidase; E.C. 1.3.3.4), catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX by the removal of six hydrogen atoms (see Figure 99-1). The product of the reaction is a porphyrin (oxidized form), in contrast to the preceding several products, which are porphyrinogens (reduced forms). This oxidation occurs readily in vitro under aerobic conditions in the absence of the enzyme. PROTO-oxidase is an integral protein of the mitochondrial inner membrane spacing and appears to be active as a dimer. PROTO-oxidase is inhibited by bilirubin, perhaps accounting for the decreased levels of the enzyme activity in Gilbert disease.

The ~5.5-kb human PROTO-oxidase gene encodes a single ~1.8-kb mRNA in all tissues, which expresses a mitochondrial-targeted polypeptide of 477 amino acids (~51 kDa) (44–46). PROTO-oxidase lacks a typical mitochondrial targeting leader sequence but is effectively targeted by its 17 N-terminal residues (36).

Mutations in the PROTO-oxidase gene result in 50% of normal enzymatic activity, causing VP, a dominantly inherited hepatic porphyria (47). Over 150 PROTO-oxidase mutations are listed in the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6). Several cases of homozygous VP have also been described (48,49).

**99.2.1.8 Ferrochelatase.** The final step in heme biosynthesis is the insertion of ferrous iron into protoporphyrin IX to form heme. This reaction is catalyzed by ferrochelatase (heme synthetase or protoheme ferrolyase; E.C. 4.99.1.1), which is associated with the inner side of the inner mitochondrial membrane. The enzyme is specific for the reduced form of iron ( $\text{Fe}^{2+}$ ) but can use other metals (e.g.  $\text{Zn}^{2+}$  and  $\text{Co}^{2+}$ ) and other 2-carboxyl porphyrins. The enzyme appears to function as a dimer in mitochondria (50), and there is suggestive evidence that the membrane domains of PROTO-oxidase dock onto the dimeric structure of ferrochelatase (51).

The ~45-kb human ferrochelatase gene encodes a 423-amino acid polypeptide including a 54-residue leader sequence (36). An iron–sulfur cluster [ $2\text{Fe}-2\text{S}$ ] has been identified in recombinant human and mouse ferrochelatase (52,53) and is thought to be essential for enzyme activity (54). The putative iron–sulfur binding site is at the C-terminus in a 30-amino acid region that contains four cysteines. Recombinant human ferrochelatase has been crystallized and diffracted to about 2 Å (55,56).

Coding region mutations in the ferrochelatase gene result in a decreased enzymatic activity, causing erythropoietic protoporphyria (EPP) (57). Over 100 ferrochelatase mutations are listed in the Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6). Clinical expression of this porphyria occurs when a disabling ferrochelatase mutation is heteroallelic with a polymorphism in intron 3 of the wild-type ferrochelatase gene that reduces expression of normal enzyme (58) or, less commonly, in individuals who inherit two mutations that impair enzyme function (e.g. coding region or splice-site mutations).

### 99.3 REGULATION OF HEME BIOSYNTHESIS

In humans, about 85% of heme is synthesized in erythroid cells to provide heme for hemoglobin, while most of the remaining heme is produced in the liver, where it is used primarily as the prosthetic group in cytochrome P450 enzymes and other hemoproteins. In the liver, the heme biosynthetic pathway is under a negative feedback control at the level of the first enzyme in the pathway, ALAS1 (the housekeeping form), by the concentration

of “free” heme (7). Heme represses the transcription and translation of liver ALAS1 mRNA, reduces ALAS1 mRNA stability (7), and interferes with the transport of the enzyme into mitochondria. High concentrations of free heme can also induce heme oxygenase and therefore stimulate heme catabolism (59). ALAS1 is inducible by many of the same chemicals that induce the hepatic cytochrome P450 enzymes. Because most of the heme synthesized in the liver is used for the synthesis of the cytochrome P450 enzymes, the induction of hepatic ALA-synthase and the cytochrome P450s occurs in a coordinated fashion. Recently, two sequence elements in the distal 5′-flanking region of the human ALAS1 gene were identified, which mediate direct transcriptional activation in response to drugs metabolized by the cytochrome P450s (60). When the regulatory “free” heme pool becomes depleted (which may occur, for example, when more heme is required for the synthesis of hemoproteins), the synthesis of ALAS1 is increased. Conversely, repression of ALAS1 synthesis results from augmentation of the regulatory heme pool. The evidence that ALA-synthase1 functions as a rate-controlling enzyme, at least in the liver, includes its relatively low  $V_{\text{max}}$  value (compared with most other enzymes in the pathway), its inducibility and short half-life, and its great sensitivity to repression by cellular heme (at concentrations below  $10^{-6}\text{M}$ ). In addition, ALAS1 mRNA is markedly increased under conditions when more heme is required by cells while expression of the other enzymes in the pathway do not change significantly (7). The low affinity of the enzyme for glycine suggests that the intracellular glycine concentration also determines the rate of ALA formation.

In erythroid cells, there are novel regulatory mechanisms for the production of the very large amounts of heme needed for hemoglobin synthesis. As noted previously, there is a separate erythroid-specific ALA-synthase gene (ALAS2) (1) and unique erythroid-specific promoters in ALA-dehydratase (11), HMB-synthase (23), and URO-synthase (61), the first four enzymes in the heme biosynthetic pathway (see Figure 99-2). The erythroid-specific gene ALAS2 on the X chromosome is expressed at high levels during erythroid differentiation. Synthesis of ALAS2, unlike ALAS1, is not repressed by hemin treatment and therefore is not regulated by the heme feedback repression. Transcriptional control of ALAS2 is exerted by erythroid-specific promoter elements in the 5′-flanking region of the gene. Translational control results from an iron-responsive element in the 5′-untranslated region of the mRNA. Transcription of the housekeeping ALAS1 gene may be downregulated during erythroid differentiation. In addition, heme regulates the rate of its synthesis in erythroid cells by controlling the transport of iron (required for ferrochelatase) into reticulocytes. Thus, the rate of iron acquisition from transferrin may be an important regulator of the erythroid heme biosynthesis (62).

These enzymes function in all cells to make heme for cytochromes and other hemoproteins. However, regulation of the heme biosynthesis in many tissues has not been the subject of intensive investigation, and some studies suggest that it may be different in tissues other than the liver and bone marrow (1).

## 99.4 CLASSIFICATION AND DIAGNOSIS OF THE PORPHYRIAS

As mentioned previously, the porphyrias can be classified as either hepatic or erythropoietic, depending on whether the heme biosynthetic intermediates that accumulate arise initially from the liver or developing erythrocytes, or as acute or cutaneous, based on their clinical manifestations. Table 99-2 lists the porphyrias, their symptoms, major biochemical abnormalities, and inheritance patterns. Further details on the deficient enzymes are given in Table 99-3. Of the five hepatic porphyrias, four of them, acute intermittent porphyria (AIP), HCP, VP, and ALA-dehydratase porphyria (ADP), are present with acute attacks of neurologic manifestations and elevated levels of one or both of the porphyrin precursors, ALA and PBG, and are thus classified as acute porphyrias. Symptoms of neuropathic abdominal pain, peripheral neuropathy, and mental disturbances develop during adult life and are more common in women than in men (1,2,4). By contrast, PCT, while classified as a hepatic porphyria, presents with blistering skin lesions and not acute attacks. HCP and VP may cause cutaneous manifestations similar to PCT, in addition to acute neurological symptoms. The erythropoietic porphyrias, CEP, and EPP, are characterized by elevations of porphyrins in bone marrow and erythrocytes and present with

cutaneous photosensitivity. X-linked protoporphyria, a variant form of EPP, has a clinical presentation identical to classic EPP. Lesions in CEP resemble PCT but are usually much more severe, whereas EPP causes a more immediate, painful, and nonblistering type of photosensitivity. Homozygous dominant forms of AIP, HCP, VP, and familial (type II) PCT (known as HEP) and the autosomal recessive ADP also have erythropoietic features (e.g. increased erythrocyte porphyrins). Rare patients who have mutations in two different heme biosynthetic genes have also been described (see “Dual Porphyrias” section).

### 99.4.1 Diagnosis

When porphyria is suspected clinically, proper laboratory testing is important to confirm or exclude the diagnosis for appropriate medical management and genetic counseling (2). Accuracy and speed are especially important in the diagnosis of an acute porphyric attack, so treatment can begin to prevent neurologic damage and even death. Tests for porphyria may be difficult to interpret because some abnormal results are seen in disorders other than the porphyrias; in particular, minimally elevated levels of urinary porphyrins may have little or no diagnostic significance.

Table 99-3 summarizes the major metabolites that accumulate in each porphyria. However, for initial diagnosis of porphyrias, it is unwise to measure all of these intermediates routinely or attempt to identify a diagnostic profile. For initial screening, we recommend relying on a limited number of tests that are sensitive, specific, and cost effective; additional testing should be done only if a screening test is positive. Testing for elevated urinary

**TABLE 99-3 Human Porphyrias Associated with Deficiencies of Specific Enzymes of the Heme Biosynthetic Pathway**

Inheritance	Deficient Enzyme	Subcellular Localization	Enzyme Activity % of Normal	Known Mutations n <sup>d</sup>	Porphyria OMIM Number <sup>a</sup>
5-ALA dehydratase-deficient	125270	AR	ALA-dehydratase	C	~5 9 porphyria (ADP)
Acute intermittent	176000	AD	HMB-synthase	C	~50244 porphyria (AIP)

PBG is especially important in screening for acute porphyrias. Active cutaneous porphyrias are readily detected by measuring total plasma porphyrin levels, although, if EPP is suspected, measurement of erythrocyte protoporphyrin is more sensitive. If a screening test result is abnormal, additional measurements are essential for establishing the specific type of porphyria (2). Urinary ALA and PBG are easily quantified by chemical methods (63), and the individual porphyrins in urine and feces can be separated and quantified by high-performance liquid chromatography. Assays are described in the literature for each of the eight heme biosynthetic enzymes, using erythrocytes, lymphocytes, cultured lymphoblasts, or cultured fibroblasts, although most are not widely available for diagnostic purposes (63). However, erythrocyte HMB-synthase activity is commonly measured to confirm the diagnosis of AIP and detect asymptomatic gene carriers.

Establishing the definitive diagnosis of a particular porphyria should include identification of the causative gene mutation(s). This is the preferred method for detecting asymptomatic relatives who carry the mutation identified in an index case (2).

### 99.4.2 5-Aminolevulinic Acid Dehydratase-Deficient Porphyria (ADP)

ALA-dehydratase-deficient porphyria (ADP) is a rare autosomal recessive acute hepatic porphyria caused by the severe deficiency of ALA-dehydratase activity (1,2). To date, only six cases have been reported with documentation by molecular methods (1,12–14). These affected homozygotes had less than 10% of normal ALA-dehydratase activity in erythrocytes, but their clinically asymptomatic parents and other heterozygous relatives had about half-normal levels of activity and did not excrete increased levels of ALA. The frequency of ADP is unknown, but the frequency of heterozygous individuals with less than 50% of normal ALA-dehydratase activity was ~2% in a screening study, in Sweden. Because there are multiple causes for deficient ALA-dehydratase activity, it is important to confirm the diagnosis of ADP by mutation analysis.

**99.4.2.1 Biochemical Aspects.** ALA-dehydratase-deficient porphyria is characterized by the markedly increased urinary excretion of ALA and coproporphyrin III and increased erythrocyte protoporphyrin (complexed with zinc). The markedly reduced erythrocyte ALA-dehydratase activity in these patients is not restored to normal by the *in vitro* addition of sulfhydryl reagents such as dithiothreitol. Immunologic studies in several cases revealed the presence of nonfunctional enzyme protein, which crossreacted with anti-ALA-dehydratase antibody.

**99.4.2.2 Molecular Aspects.** Molecular studies of ADP patients have identified nine-point mutations, two splice-site mutations, a two-base deletion, and

two different base changes at position -11 bp upstream of the exon 3 start site in the ALA-dehydratase gene (Human Gene Mutation Database; [www.hgmd.org](http://www.hgmd.org)) (6,12,14,64). The parents in each case were not consanguineous, and the index cases had inherited a different ALA-dehydratase mutation from each parent. In addition, a point mutation, F12L, was identified in an asymptomatic Swedish girl who had 12% of normal erythrocyte ALA-dehydratase activity (64,65).

The molecular basis of the ALAD2 polymorphism is a substitution of a lysine by an asparagine at residue 95 (K95N). To date, ADP has not been diagnosed prenatally, but this should be possible by determination of the ALA-dehydratase specific molecular lesions in cultured chorionic villi or amniocytes.

**99.4.2.3 Clinical Manifestations.** The onset, severity, and clinical presentations of ADP are variable, presumably depending on the amount of residual ALA-dehydratase activity. All patients had significantly elevated levels of plasma and urinary ALA, with little increase in PBG concentrations and ALA-dehydratase activities of 10% or less of normal. Four reported patients were male adolescents with symptoms resembling those of AIP, including abdominal pain and neuropathy (12–14). The third patient was an infant with more severe disease, including failure to thrive beginning at birth. The earlier age of onset and more severe manifestations in this patient reflect a more significant deficiency of ALA-dehydratase activity (64). Another patient was essentially normal until age 63, when he developed an acute motor polyneuropathy that was associated with a myeloproliferative disorder. This patient was heterozygous for an ALA-dehydratase mutation that presumably was present in erythroblasts that underwent clonal expansion due to the bone marrow malignancy (66).

**99.4.2.4 Differential Diagnosis.** Lead, styrene, and succinylacetone (which is structurally similar to ALA and accumulates in hereditary tyrosinemia type 1 due to fumarylacetoacetase deficiency) inhibit ALA-dehydratase, causing increased urinary excretion of ALA and coproporphyrin, and clinical manifestations that resemble those of the acute porphyrias. Idiopathic acquired ALA-dehydratase deficiency has also been reported. Therefore, these known causes of ALA-dehydratase deficiency should be considered in the differential diagnosis of ADP and the diagnosis of ADP confirmed by demonstrating the underlying ALA-dehydratase mutations.

**99.4.2.5 Treatment.** Because of the small number of ADP patients, there is a limited experience in treatment. Glucose has shown little benefit. Hemin therapy has helped the clinical symptoms in patients with adolescent-onset ADP (12,14,67) and was beneficial for preventing symptoms in one patient (12). A severely affected ADP child did not improve significantly with glucose, hemin, or liver transplant (13,64).

### 99.4.3 Acute Intermittent Porphyria

Acute intermittent porphyria (AIP) is an autosomal dominant acute hepatic porphyria resulting from half-normal levels of HMB-synthase activity. The disease occurs in all ethnic groups with an estimated frequency of individuals with acute attacks of 1 to 2 per 100,000 in most European countries, making it the most common acute porphyria (3,23). It is estimated that less than 10% of individuals with an HMB-synthase mutation have acute attacks (3). A survey of 3350 healthy French blood donors identified two with HMB-synthase gene mutations for a frequency of 1 in 1750, indicating that clinical expression is low (3). The highly variable symptoms and signs include visceral, autonomic, peripheral, and central nervous system manifestations. Activation of the disease is clearly related to ecogenic factors, as its expression is usually triggered by hormonal, metabolic, dietary, or environmental factors, which can precipitate acute attacks. Symptomatic patients always have increased urinary excretion of the porphyrin precursors ALA and PBG. However, the great majority of heterozygotes with HMB-synthase deficiency remains clinically asymptomatic (“latent” or presymptomatic) and may never have increased urinary ALA and PBG excretions.

**99.4.3.1 Biochemical Aspects.** The metabolic defect in AIP is the half-normal activity of HMB-synthase. For most HMB-synthase mutations, the enzyme activity is half-normal in all tissues. However, about 5% of patients have normal HMB-synthase activity in their erythrocytes (23) because they have mutations in or near exon 1 (see “Molecular Aspects” section). Moreover, the range of erythrocyte HMB-synthase activities in patients with classic AIP overlaps the range for normal individuals, as discussed later. Hepatic HMB-synthase activity in patients with active and latent AIP has not been compared.

**99.4.3.2 Molecular Aspects.** To date, over 300 mutations have been identified, most being either point or splice-site mutations (Human Gene Mutation Database ([www.hgmd.org](http://www.hgmd.org)) (6). Most are private, occurring in only one or a few unrelated families. Exceptions include W198X and R116W, which are common in the Swedish and Dutch populations, respectively and G111R, which was found in Argentinean AIP patients (68). A study of 143 Russian and Finnish AIP patients identified genotype-phenotype correlations (69). Based on the crystal structure of *E. coli* HMB-synthase, effects of specific AIP mutations on the human enzyme structure and function have been predicted (24,25).

In a variant form of AIP, molecular studies have identified mutations that impair splicing of exon 1 to exon 3, thereby preventing the formation of the housekeeping but not the erythroid-specific transcript (1,6,23). Other exon 1 mutations alter the initiation of the translation codon, thereby precluding the translation of the housekeeping transcript (70). These tissue-specific

splicing and initiation of translation mutations provide an explanation for the deficient activity in the liver and other nonerythroid tissues in these cases, while the levels of HMB-synthase activity in erythrocytes remain normal. This variant form of AIP can be suspected in a patient with increased PBG, normal erythrocyte HMB-synthase, and laboratory findings that exclude HCP and VP, and mutation analysis is required for confirmation.

Homozygous dominant AIP is a rare form of AIP in which patients have mutations in both of their HMB-synthase alleles and, therefore, very low (<2%) enzyme activity. The disease has been described in a Dutch girl, two young British siblings, and a Spanish boy (71,72). In these homozygous-affected patients, the disease presented in infancy with failure to thrive, developmental delay, bilateral cataracts, and/or hepatosplenomegaly. Interestingly, all these patients’ mutations (R167W, R167Q, and R172Q) were in exon 10 within 5 bases of each other.

**99.4.3.3 Clinical Manifestations.** Acute intermittent porphyria is characterized by neurovisceral disturbances that develop after puberty in a minority of heterozygotes with HMB-synthase deficiency. Symptoms and signs are nonspecific and require a high index of suspicion to suggest the proper diagnosis (2). Abdominal pain, which is the most common symptom, is usually steady and poorly localized, but may be cramping, and is accompanied by nausea and vomiting. Constipation and signs of ileus, including abdominal distension and decreased bowel sounds, are common. However, increased bowel sounds and diarrhea may also occur. These abdominal manifestations are neurologic rather than inflammatory, and therefore tenderness, fever, and leukocytosis are generally absent or mild. Tachycardia, hypertension, restlessness, fine tremors, and excess sweating may be explained by sympathetic overactivity. Dysuria and bladder dysfunction are common, and urinary retention may require catheterization. Chronic hypertension and impaired renal function may develop over a long term. AIP is also commonly associated with mild abnormalities in liver function and the risk of more advanced liver disease and hepatocellular carcinoma is increased.

Peripheral neuropathy in AIP is primarily motor and appears to result from axonal degeneration rather than demyelination. However, paresis does not develop in all patients who suffer from acute attacks, even when abdominal symptoms are severe. Muscle weakness most commonly begins proximally, more often in the arms than in the legs. Tendon reflexes may be normal or hyperactive in early disease stages but are usually decreased or absent with advanced neuropathy. Paresis can be asymmetric and focal. Cranial nerves, most commonly the tenth and seventh, can be affected. Rarely, involvement of the optic nerves or occipital lobes may produce blindness. Extremity pain and paresthesia and areas of loss of sensation are indications of sensory involvement. Muscle weakness can progress to respiratory and bulbar

paralysis and death, but this seldom occurs unless the porphyria is not recognized, harmful drugs are not discontinued, or appropriate treatment is not instituted. Sudden death, presumably due to cardiac arrhythmia, also may occur. Complete recovery even from severe neuropathy over a period of a year or longer is possible.

Central nervous system involvement during acute attacks may be manifested as anxiety, insomnia, depression, disorientation, hallucinations, and paranoia and may suggest a primary mental disorder. Some patients have been mistakenly regarded as hysterical. Depression and other mental symptoms may be chronic in AIP patients. However, it has not been proved that the prevalence of AIP is higher in psychiatric patients than in the general population. Seizures may occur as part of the acute neurologic manifestations of AIP or as a result of hyponatremia, which have been observed and may result from a variety of causes, including inappropriate antidiuretic hormone (ADH) secretion, gastrointestinal losses secondary to vomiting and diarrhea, poor intake, or excess renal sodium loss. Antiseizure drugs are problematic because almost all have at least some potential for exacerbating AIP, with clonazepam being less likely to do so than phenytoin or barbiturates. Improved overall morbidity and mortality in acute porphyrias in the past 20 to 30 years is attributable to earlier detection, less use of barbiturates and sulfonamides in clinical practice, and better treatment of acute attacks (4).

**99.4.3.4 Etiology and Pathogenesis.** Most of the factors known to precipitate acute porphyric attacks have the potential to induce the synthesis of ALAS1 in the liver, thereby increasing the accumulation of ALA, PBG, and other heme pathway intermediates. Normally, a half-normal amount of hepatic HMB-synthase activity is sufficient to avoid any accumulation of PBG. However, when certain environmental, metabolic, and hormonal factors increase the flux of ALA, PBG, and porphyrinogens through the pathway, the partially deficient activity of HMB-synthase may be insufficient to metabolize the increased amounts of PBG.

The etiology of the neurologic manifestations in AIP is not established (73). The possibility that ALA or PBG might be neurotoxic is favored by the increased production of porphyrin precursors during acute porphyric attacks. ALA is taken up by most tissues more readily than PBG, which appears to more readily cross the blood-brain barrier. These intermediates may be converted in vivo to other substances, including porphyrins, which may have neurotoxic potential. The fact that AIP, HCP, VP, ADP, plumbism, and hereditary tyrosinemia are all associated with increased ALA and similar neurologic manifestations favors a neuropathic role for ALA. Moreover, ALA is structurally analogous to  $\gamma$ -aminobutyric acid (GABA) and can interact with GABA receptors (73).

Alternatively, deficient HMB-synthase activity could lead to a functional heme deficiency in the nervous

system, or predispose to unsaturation of hepatic tryptophan pyrrolase, thus leading to altered tryptophan delivery to nervous tissue. Experimental observations regarding these and other possible mechanisms for neurologic dysfunction in the acute porphyrias are reviewed in more detail, elsewhere (2,72,73).

A mouse model in which HMB-synthase deficiency was introduced by gene targeting has been developed (74,75). These animals, when treated with a barbiturate, have impaired motor function, ataxia, increased levels of ALA in brain and plasma, and decreased heme saturation of liver tryptophan pyrrolase. Motor neuropathy can develop in these mice with normal or only slightly increased plasma or urinary ALA, suggesting a role for heme deficiency in nervous tissue (73,74). Studies of the brain MRIs of children with homozygous AIP have suggested damage primarily in white matter that was myelinated postnatally, while tracks that myelinated prenatally were normal (72). These findings suggest that a postnatal toxin such as elevated ALA or PBG rather than heme deficiency caused nervous tissue damage since prenatally elevated ALA and PBG would cross the placenta and be excreted in the mother's urine. Also, the recent finding that a hepatic transplant cured a woman with AIP who had 37 acute attacks in 29 months pre-transplant supports the notion that the acute attacks result from the excess porphyrin precursors produced in the liver (76).

**99.4.3.5 Precipitating Factors.** Certain clinical features of AIP suggest that endogenous steroid hormones are important precipitating factors (1). These include (i) the rarity of symptoms and excess porphyrin precursor excretion before puberty; (ii) more frequent clinical expression in women than in men; (iii) premenstrual attacks of the disease in some women and their prevention by gonadotropin-releasing hormone (GnRH) analogues; (iv) exacerbation of AIP due to exogenous steroids, such as oral contraceptive preparations; and (v) the presence of more subtle abnormalities in steroid hormone metabolism, such as a deficiency of hepatic steroid 5 $\alpha$ -reductase activity. The latter can predispose to the excess production of steroid hormone metabolites that are inducers of hepatic ALAS1.

**99.4.3.5.1 Pregnancy Is Usually Well Tolerated.** However, some women with AIP do experience an increased frequency of attacks during pregnancy. Earlier reports that worsening symptoms during pregnancy are more common may have been due in part to the use of barbiturates and perhaps to reduced caloric intake. Thus, pregnancy is not contraindicated in most women with AIP if harmful drugs are avoided and attention is given to proper nutrition.

Drugs are an important cause of AIP attacks, and the avoidance of harmful drugs can favorably impact the disease course. The major drugs known or strongly suspected by most observers to be harmful in the acute porphyrias, as well as drugs that are known to be safe, are listed in Table 99-4 and include most anticonvulsants,

**TABLE 99-4** Some Major Drugs Considered Unsafe and Safe in Acute Porphyrrias<sup>a</sup>

Unsafe	Safe
Alcohol	Acetaminophen
Barbiturates <sup>b</sup>	Aspirin
Carbamazepine <sup>b</sup>	Atropine
Carisoprodol <sup>b</sup>	Bromides
Clonazepam (high doses)	
Danazol <sup>b</sup>	Erythropoietin <sup>b,c</sup>
Diclofenac and possibly other	Gabapentin NSAIDs <sup>b</sup>
Ergots	Glucocorticoids
Estrogens <sup>b,d</sup>	Insulin
Ethchlorvynol <sup>b</sup>	Narcotic analgesics
Glutethimide <sup>b</sup>	Penicillin and derivatives
Griseofulvin <sup>b</sup>	
Mephenytoin	Ranitidine <sup>b,c</sup>
Meprobamate <sup>b</sup> (also mebutamate <sup>b</sup> ,	Streptomycin tybutamate <sup>b</sup> )
Methyprylon	
Metoclopramide <sup>b</sup>	
Phenytoin <sup>b</sup>	
Primidone <sup>b</sup>	
Progesterone and synthetic progestins <sup>b</sup>	
Pyrazinamide <sup>b</sup>	
Pyrazolones (aminopyrine, antipyrine)	
Rifampin <sup>b</sup>	
Succinimides (ethosuximide, methsuximide)	
Sulfonamide antibiotics <sup>b</sup>	
Valproic acid <sup>b</sup>	

NSAIDs, nonsteroidal anti-inflammatory drugs.

<sup>a</sup>More extensive list of drugs and their status are available in Anderson KE, Sassa S, Bishop DF, et al. (2001) Disorders of heme biosynthesis: X-linked sideroblastic anemias and the porphyrias. In Scriver CR, Beaudet AL, Sly WS, Valle D (eds): The Metabolic and Molecular Basis of Inherited Disease, 8th ed. McGraw-Hill, New York, p 2991; also see Web sites ([www.porphyrifoundation.com](http://www.porphyrifoundation.com); [www.porphyrria-europe.com](http://www.porphyrria-europe.com)).

<sup>b</sup>Porphyria is listed as a contraindication, warning, precaution, or adverse effect in the U.S. labeling for these drugs. For drugs listed as unsafe, absence of such cautionary statements in the U.S. labeling does not imply lower risk.

<sup>c</sup>Although porphyria is listed as a precaution in the U.S. labeling, these drugs are regarded as safe by other sources.

<sup>d</sup>Estrogens have been regarded as harmful, mostly from experience with estrogen–progestin combinations and because they can exacerbate porphyria cutanea tarda (PCT). Although the evidence that they exacerbate acute porphyrias is weak, they should be used with caution. Low doses of estrogen (e.g. transdermal) have been used safely to prevent side effects of GnRH analogues in women with cyclic attacks.

barbiturates, sulfonamide antibiotics, and metoclopramide. Other reviews and more extensive lists of drugs that are harmful or safe are published (1,2) or available through the American Porphyria Foundation Web site ([www.porphyrifoundation.com](http://www.porphyrifoundation.com)) and the European Porphyria Initiative Web site ([www.porphyrria-europe.org](http://www.porphyrria-europe.org)). Most porphyrogenic drugs (e.g. barbiturates) exert their action by induction of hepatic ALAS1, cytochromes P450, and heme synthesis in the liver. Smoking

results in exposure to chemicals that induce cytochrome P450 enzymes and heme synthesis in the liver, and may increase the risk of attacks.

A large retrospective study of risk from anesthetic use in AIP concluded that barbiturates or other inducing drugs are quite frequently detrimental in patients who have already displayed porphyric symptoms, but that they seldom exacerbate latent disease (77). Drugs are only rarely reported to cause acute symptoms in children, who have naturally low levels of endogenous hormones. Such observations indicate that attacks are likely to be due to the additive effects of more than one precipitating factor.

Attacks can also be provoked by intercurrent infections and other illnesses and by major surgery. The mechanisms are not understood but may involve metabolic stress, impaired nutrition, and the increased production of steroid hormones and their ALA-synthase-inducing metabolites. A low caloric intake, usually instituted in an effort to lose weight, is a common contributing cause of acute attacks. Caloric or carbohydrate restriction can precipitate acute symptoms of AIP and increase porphyrin precursor excretion. Recent findings indicate that hepatic ALAS1 is regulated by the peroxisome proliferator-activated receptor  $\gamma$  coactivator 1 $\alpha$  (PGC-1 $\alpha$ ), which may represent an important link between nutritional status and acute porphyrias (78).

**99.4.3.6 Laboratory Evaluations.** Urinary excretion of porphyrin precursors is markedly increased during acute attacks of AIP. Fecal porphyrins are usually normal or minimally increased in AIP, which helps to distinguish this disorder from HCP and VP. Because ALA and PBG are colorless, the reddish urine observed in AIP is due to increased porphyrins, which can form nonenzymatically from PBG. Brownish discoloration may be due to porphobilin, a degradation product of PBG, or dipyrromethenes. A normal result of a quantitative test for urinary PBG during a symptomatic period virtually excludes acute porphyria as a cause for concurrent symptoms. An exception is ADP, in which there is an increase in ALA, but not PBG (2).

It is useful to follow ALA and PBG excretion in a symptomatic patient because the concentrations of these compounds generally decrease with clinical improvement. Such decreases are particularly dramatic after heme infusions. But, it is unusual for excretion of ALA and PBG to decrease to normal levels and remain normal unless the disease becomes clinically latent for a prolonged period. In contrast, ALA and PBG levels are often less elevated and may decrease to normal soon after acute attacks of HCP and VP.

The diagnosis of AIP heterozygotes can be confirmed by the finding of half-normal levels of erythrocyte HMB-synthase. However, normal erythrocyte HMB-synthase activity does not exclude AIP, as some mutations in the HMB-synthase gene lead to a deficiency of the enzyme in the liver and other organs, but not in erythrocytes

(1,78,79). A definitive diagnosis may also be precluded because of the following: (i) the normal range for erythrocyte HMB-synthase activity is wide (up to threefold) and low normal and high carrier values overlap; (ii) the enzyme activity is much higher in younger than older erythrocytes and therefore increases when erythropoiesis is stimulated; and (iii) improper processing, storing, and shipping of blood samples can decrease enzyme activity (2). The specific molecular defect in the HMB-synthase gene should be identified in each family in order to provide accurate diagnosis of presymptomatic AIP heterozygotes (2). Most HMB-synthase mutations are family-specific, with a few notable exceptions, where particular mutations have been transmitted over generations from single founders (1). Patients with AIP should have genetic counseling and be encouraged to inform family members about the disease and its genetics. Knowledge of genetic status enables family members to make informed decisions about lifestyle and to know the potential risks of certain drugs, preferably before the development of an acute illness. However, latent porphyria should not be construed as a health risk that limits health or life insurance. Prenatal diagnosis of AIP has been performed by enzymatic assay but is seldom indicated because the outlook for most carriers is favorable.

#### 99.4.3.7 Treatment.

**99.4.3.7.1 Supportive and Symptomatic Treatment.** Hospitalization may be required: for evaluation and treatment of severe pain, nausea, and vomiting; for administration of intravenous fluids, electrolytes, glucose, and hemin; and for close observation for electrolyte derangements and neurologic complications. Medications taken by the patient should be reviewed immediately and those identified as harmful stopped, if at all possible. Narcotic analgesics are usually required for abdominal pain, and small to moderate doses of a phenothiazine are indicated for nausea, vomiting, anxiety, and restlessness.

Carbohydrate loading provides nutritional replacement, has some repressive effect on hepatic ALA synthase, but is less effective than hemin. It may suffice for mild attacks in patients with low narcotic requirements and without hyponatremia or paresis. Sucrose, glucose polymers, or carbohydrate-rich foods may be given to patients without abdominal distention and/or ileus and who can tolerate oral treatment. The standard intravenous regimen is 10% glucose for a total of at least 300–500 g daily. However, large volumes of 10% glucose may increase the risk of hyponatremia. Severe or prolonged attacks should be treated with hemin and may also require more nearly complete nutritional support.

Tachycardia and systemic arterial hypertension may be treated cautiously with  $\beta$ -adrenergic blocking agents, but they may be hazardous in patients with hypovolemia, in whom increased catecholamine secretion may be an important compensatory mechanism (2). Seizures

are difficult to treat because almost all antiseizure drugs can exacerbate an attack. Gabapentin, and probably vigabatrin, can be given safely and benzodiazepines are relatively safe. Careful correction of hyponatremia and hypomagnesemia is important, particularly when associated with seizures.

**99.4.3.7.2 Hemin Therapy.** Intravenous hemin addresses the underlying pathophysiology by repressing hepatic ALAS1, hence decreasing the overproduction of ALA and PBG. Hemin given intravenously at moderate dose (3–4 mg/kg day for 4 days) is mostly taken up in the liver, and can at least transiently replenish the depleted heme pool that regulates the synthesis of ALAS1. It cannot be given orally because it is catabolized by heme oxygenase during intestinal absorption.

Hemin therapy should be started early (2). Although product labeling recommends an initial trial of intravenous glucose, hemin is the preferred therapy (80–82). The standard regimen is 3–4 mg of hemin per kilogram of body weight, infused intravenously once daily for 4 days. Hemin (Panhematin®), Lundbeck Pharmaceuticals, is available in the United States as lyophilized hydroxyheme (hematin) for reconstitution with sterile water just before infusion, and it is approved by the FDA for amelioration of acute porphyric attacks. Degradation products form rapidly in vitro when this product is reconstituted with sterile water, as recommended in product labeling, and these adhere to endothelial cells, platelets, and coagulation factors and cause a transient anticoagulant effect and often a phlebitis at the site of infusion. With repeated administration, phlebitis can compromise venous access. It is recommended that lyophilized hemin be reconstituted with human albumin to enhance stability (2). Another hemin preparation, heme arginate, is more stable in solution but is not available in the United States.

Reconstitution of lyophilized hydroxyheme with albumin enhances stability of lyophilized hemin, decreases the incidence of phlebitis, and may enhance efficacy. Other uncommon reported side effects of hemin include fever, aching, malaise, hemolysis, a case of circulatory collapse that resulted in full recovery after subsequent hemin infusions, and one case of transitory renal failure after a dosage of 1000 mg. Experience indicates that hemin can be administered safely during pregnancy.

Patients should be monitored closely during management of acute attacks for complications and signs of progression of acute porphyria such as electrolyte imbalance, acute psychiatric manifestations, muscle weakness, bladder retention, and ileus (2). Spirometry is sometimes indicated daily to detect respiratory impairment at least until the attack begins to resolve. Since patients with respiratory impairment can deteriorate rapidly, it is recommended they be placed in intensive care. ALA and PBG usually fall to normal whether therapy is started early or late, but this does not necessarily predict a clinical response.

Clinical improvement may occur within 1 to 2 days if hemin is started early in an attack. Patients can sometimes be discharged from the hospital within several days, although we recommend completion of the standard 4-day treatment course in the outpatient clinic. If initiated late, efficacy of hemin may not be immediately apparent because neuronal damage may already be advanced and slow to recover. In such cases, treatment for longer than 4 days should be considered, although the evidence that this improves the outcome is lacking. Hemin is seldom effective for chronic symptoms. Hemin therapy can be given in outpatient settings or in the home, if this facilitates prompt therapy and reduces medical care costs in patients with frequent attacks.

Chronic renal failure has developed in some AIP patients and required renal transplantation. This may be caused by the development of chronic hypertension and prevented by control of blood pressure. AIP also increases the risk of chronic liver disease and especially hepatocellular carcinoma. These tumors seldom increase serum  $\alpha$ -fetoprotein levels. Therefore, periodic screening by ultrasound or another hepatic imaging technique is recommended.

**99.4.3.7.3 Transplantation.** An allogeneic liver transplant was performed on a 19-year-old female AIP heterozygote who had 37 acute attacks in the 29 months prior to transplantation. Posttransplantation, her elevated urinary ALA and PBG levels returned to normal in 24 hours, and she did not experience acute neurologic attacks for more than 18 months posttransplant (76). Two AIP patients had combined liver and kidney transplants secondary to uncontrolled acute porphyria attacks, chronic peripheral neuropathy, and renal failure, requiring dialysis. Both patients had marked improvement with no attacks and normal urinary PBG levels posttransplantation, as well as improvement of their neuropathic manifestations (83). It should be noted that liver transplantation is a high-risk procedure and should not be considered as an established treatment for acute porphyrias. Recently, liver-directed gene therapy has been proven successful in the prevention of drug-induced biochemical attacks in a murine model of human AIP (84).

**99.4.3.8 Prevention of Acute Attacks and Later Complications.** Prevention of future attacks requires identifying precipitating factors. Educating the patient to avoid alcohol, smoking, and drugs that can induce exacerbations (see Table 99-4) is important, as in maintaining adequate nutrition. Lists of safe and harmful drugs are available (see previous discussion for references) but these are not infallible. Medical alert bracelets and wallet cards can help notify emergency medical personnel and ensure that unsafe drugs are not given to patients in emergencies. Some patients have frequent attacks even after exacerbating factors are removed, possibly because of unidentified modifier genes or environmental or endogenous precipitating factors. These patients should

be evaluated by a nutritionist and follow a well-balanced diet with sufficient calories to maintain weight.

Gonadotropin-releasing hormone (GnRH) analogues can be highly effective for women with frequent cyclic attacks when symptoms are confined to the luteal phase of the menstrual cycle (1). The low-dose estrogen patch has been successful in reducing side effects when treatment beyond six months is contemplated. Gynecological examinations and bone density determinations are advised every 6 months during treatment. Continued need can be assessed every 1 to 2 years by stopping the treatment.

Pregnancy increases levels of progesterone, a potent inducer of heme biosynthesis in the liver but nevertheless is well tolerated in most women with acute porphyria. For example, in a large series of women with AIP or VP who had 176 deliveries, porphyric symptoms were absent in 92% of their pregnancies (85). Because some women experience more frequent attacks during pregnancy, counseling women who wish to become pregnant must be individualized.

Recurrent noncyclic attacks are sometimes prevented by weekly or biweekly infusions of single doses of hemin (3–4 mg/kg). Frequent treatment with hemin has a theoretic risk of iron overload (100 mg of hemin contains 8 mg of iron); therefore, serum ferritin levels should be monitored. In selected rare instances of severe, unremitting symptomatic disease, consideration might be given to orthotopic liver transplantation (76). Transplantation of hepatocytes or specific gene replacement therapy is a possible future therapeutic strategy.

## 99.4.4 Congenital Erythropoietic Porphyrria

Congenital erythropoietic porphyria (CEP), also known as Günther disease, is an autosomal recessive disorder due to the markedly deficient activity of URO-synthase, the fourth enzyme in the heme biosynthetic pathway. CEP is panethnic, and as of 2000, about 160 cases were reported (28,86).

**99.4.4.1 Biochemical Aspects.** The deficient activity of URO-synthase is the enzymatic defect in CEP. Affected homozygotes have markedly deficient, but not absent, URO-synthase activity, as sufficient enzyme is required to produce uroporphyrinogen III for normal (or even increased) rates of heme production. Most CEP patients have less than 10% of normal erythrocyte URO-synthase activity. The deficient URO-synthase activity leads to the accumulation of the substrate, hydroxymethylbilane (HMB), most of which is converted nonenzymatically to uroporphyrinogen I. Although uroporphyrinogen I can undergo decarboxylation by URO-decarboxylase to form hepta-, hexa- and pentacarboxyl porphyrinogen I and finally coproporphyrinogen I, further metabolism cannot proceed because the next enzyme in the pathway, COPRO-oxidase, is stereospecific for the III isomer.

Therefore, the isomer I porphyrins are nonphysiologic, in that they cannot be metabolized to heme, and are pathogenic when they accumulate in large amounts and undergo auto-oxidization to their corresponding porphyrins. In patients with CEP, the large amounts of isomer I porphyrinogens that accumulate in bone marrow erythroid precursors (especially normoblasts and reticulocytes) and erythrocytes undergo auto-oxidation to the corresponding porphyrins, which damage erythrocytes, cause cutaneous photosensitivity, are deposited in tissues and bones, and are excreted in large amounts in the urine and feces.

**99.4.4.2 Molecular Aspects.** The isolation and characterization of the URO-synthase cDNA and genomic sequences have permitted the identification of mutations in CEP patients (26,28,87). Over 39 mutations have been detected in unrelated CEP families including missense and nonsense mutations, large and small deletions and insertions, splicing defects, intronic branch point mutations, and erythroid-specific promoter mutations (6). Most mutations have been detected in only one or a few unrelated families, except for C73R, which has been found in about 33% of the alleles studied, L4F in 7%, and T228M in 6% (28). The recent discovery of alternative housekeeping and erythroid-specific promoters in the human URO-synthase gene facilitated the identification of four-point mutations within a 20-bp region of the erythroid-specific promoter in six unrelated CEP probands (26,88). These mutations included a -70T to C transition altering a GATA-1 binding element, a -76 G to A transition, a -86C to A transversion in three unrelated patients, and a -90C to A transversion that altered a putative CP2 binding element. These four pathogenic erythroid promoter mutations impaired erythroid-specific transcription, caused CEP, and identified functionally important GATA1 and CP2 transcriptional binding elements for erythroid-specific heme biosynthesis. To date, these are the only known promoter mutations in the erythropoietic porphyrias. For a review of URO-synthase mutations causing CEP, see (6,28).

Genotype-phenotype correlations are possible in CEP once a patient's mutations are known. Prokaryotic expression and gene promoter-reporter systems have been used to determine the *in vitro* levels of enzymatic activity expressed by the missense mutations and the promoter function of mutations in the erythroid-specific promoter. The prokaryotic expression of URO-synthase constructs containing missense mutations resulted in levels of enzymatic activity that ranged from essentially nondetectable to about 35% of the mean activity expressed by the wild-type allele in *E. coli*. The effect of the four promoter mutations on transcription also was assessed *in vitro* by determining the luciferase activity of each lesion using promoter-reporter gene constructs in uninduced and induced (with hemin) K562 erythroleukemia cells (88).

For genotype-phenotype correlations, a series of CEP patients were classified as very mild to severely affected, based on age, degree of hemolytic anemia, organomegaly, osteopenia, and cutaneous involvement (28). Homoallelism for the most common allele, C73R, was correlated with the most severe phenotype, nonimmune hydrops fetalis and/or transfusion dependency from birth. Consistent with the severe phenotype of C73R/C73R homozygotes, expression of the C73R allele in *E. coli* resulted in the detection of less than 1% of the activity expressed by the wild-type allele. The fact that the C73R/C73R homozygotes are viable and do not die early in fetal life indicates that the mutant enzyme retains a very small amount of residual activity that is sufficient to produce enough heme for the biosynthesis of hemoglobin and other essential hemoproteins. Alternatively, if the C73R mutation produced only nonfunctional or barely functional enzyme, then the fact that affected fetuses survive suggests the possibility of another gene that is responsible for URO-synthase activity during development. However, knockout mice homozygous for a null mutation in the URO-synthase gene died early in embryogenesis, indicating that the total deficiency of URO-synthase activity was an embryonic lethal (89).

Patients heteroallelic for C73R and another mutation that expressed little residual activity, such as P53L, also resulted in a severe or moderately severe phenotype. Patients heteroallelic for mutations that expressed more residual activity such as A104V (7.7% of normal activity), A66V (14.5% of normal activity), and V82F (35% of normal activity) had milder forms of CEP, even if the other allele was C73R or another mutation that did not express detectable activity (e.g. nonsense and frameshift mutations). For example, a teenage boy whose genotype was C73R/A66V had only mild cutaneous involvement. Genotype-phenotype correlations for CEP probands with erythroid promoter mutations also have been made (88). For example, a proband heterozygous for a promoter mutation with low activity (-70C) and for C73R had the severe nonimmune hydrops fetalis phenotype, while a proband with the C73R mutation in one allele but with a promoter mutation with more activity (-76A) in the other allele had a mild cutaneous disease phenotype (88). As additional mutations are identified and expressed, more information will become available to evaluate genotype/phenotype correlations.

Affected fetuses can be detected *in utero* by determining the uroporphyrin I levels in amniotic fluid, the URO-synthase activity in cultured amniotic fluid cells or chorionic villi, and/or by molecular analysis in families where the URO-synthase mutation(s) has been identified (90), or by a combination of these methods (91).

**99.4.4.3 Clinical Manifestations.** The age at onset and clinical severity of CEP are highly variable, ranging from nonimmune hydrops fetalis due to severe hemolytic anemia *in utero* to milder, later-onset forms that have only cutaneous lesions in adult life (28,87). At least some

of the late onset cases have been associated with myeloproliferative disorders, in which a clone of erythroid cells carries expresses URO-synthase deficiency (66). A number of factors are responsible for the phenotypic variability including (i) the amount of residual URO-synthase activity, (ii) the degree of hemolysis and consequent stimulation of erythropoiesis, and (iii) exposure to UV light. Therefore, as in other porphyrias, an interplay of environmental factors with the deficient enzyme activity determines the clinical expression of disease. Life expectancy may be diminished in more severely affected patients owing to the hematologic complications and the increased risk of infection (28).

The major debilitating clinical features of CEP are photosensitivity and anemia. Severe cutaneous photosensitivity begins in early infancy and is manifested by increased friability and blistering of the epidermis on the hands and face and other sun-exposed areas. Skin manifestations resemble those of PCT, but with the much higher levels of porphyrins in plasma are usually much more severe. Bullae and vesicles contain serous fluid and are prone to rupture and infection. The skin may be thickened, with areas of hypo- and hyperpigmentation. Hypertrichosis of the face and extremities is often prominent. Recurrent vesicles and secondary infection can lead to cutaneous scarring and deformities, as well as to loss of digits and facial features such as eyelids, nose, and ears. Corneal scarring can lead to blindness. Porphyrins deposited in the teeth produce red fluorescence on exposure to long-wavelength UV light and a reddish-brown color in natural light, termed erythrodontia. Bone demineralization may result from expansion of the hyperplastic bone marrow and associated porphyrin deposition in bone (1,92).

Hemolysis is accompanied by anisocytosis, poikilocytosis, polychromasia, basophilic stippling, reticulocytosis, increased nucleated red cells, decreased serum haptoglobin, increased unconjugated bilirubin, increased fecal urobilinogen, and increased plasma iron turnover, and probably results from the accumulated porphyrins in erythrocytes. Development of secondary splenomegaly may contribute further to the anemia and may also result in leukopenia and thrombocytopenia. The latter is sometimes associated with significant bleeding, and in such cases, splenectomy may be beneficial. Hemolytic anemia is especially severe if the bone marrow does not compensate, and some patients are transfusion dependent. For example, CEP-genotype C73R/C73R usually presents in utero with hemolysis and nonimmune hydrops, which if recognized can be treated by intrauterine transfusions.

To better understand the pathophysiology and for studying treatment modalities, mouse models of CEP using knock-in techniques have been developed in which the mice have low URO-synthase activity and clinical symptoms, including erythrodontia, characteristic light-induced cutaneous involvement, hepatosplenomegaly, and hemolytic anemia (93,94).

**99.4.4.4 Laboratory Evaluation.** CEP should be suspected as a cause of nonimmune hydrops and in infants or young children with severe photosensitivity and markedly increased urinary and plasma porphyrins. Reddish urine in the diaper shortly after birth is often the first suggestion of this disease. Milder cases of CEP may be developed later in life in the presence of a myeloproliferative disorder and resemble PCT. Accumulation of isomer I porphyrins, especially uroporphyrin I and coproporphyrin I in bone marrow, erythrocytes, plasma, and urine is the biochemical hallmark of the disease. Urinary porphyrins are primarily uroporphyrin I and coproporphyrin I, the intermediate 7-, 6-, and 5-carboxyl porphyrins being excreted in excess as well. Although there is a great predominance of type I isomers, type III isomers are also increased. Protoporphyrin IX is sometimes the predominant porphyrin in erythrocytes in CEP, as in other autosomal recessive porphyrias. Urinary ALA and PBG are not increased. Fecal porphyrins are markedly increased, with a predominance of coproporphyrin I.

URO-synthase activity can be measured in erythrocytes and cultured cells using either direct or coupled enzyme assays (95). CEP should be differentiated from other porphyrias with cutaneous photosensitivity. For example, HEP often mimics CEP clinically but is the homozygous dominant form of URO-decarboxylase deficiency. HEP is distinguishable from CEP by porphyrin patterns resembling PCT, including high levels of isocoproporphyrin in feces and urine and markedly decreased URO-decarboxylase activity in erythrocytes. Very rare homozygous forms of VP and HCP also may be characterized by photosensitivity in childhood and increased erythrocyte porphyrins.

**99.4.4.5 Treatment.** Skin Protection. Protection of the skin from sunlight and minor trauma is essential. Sunscreen lotions and b-carotene are sometimes beneficial. Bacterial infections that complicate cutaneous blisters require timely treatment in an effort to prevent scarring and mutilation. Severe infections such as cellulitis and bacteremia may require intravenous antibiotics.

**99.4.4.5.1 Marrow Suppression.** Frequent blood transfusions are sometimes essential for severe anemia. Transfusions repeated frequently enough to suppress erythropoiesis, and thereby decrease porphyrin production, can greatly reduce porphyrin levels and photosensitivity. Such therapy is likely to be successful if the hematocrit remains above 35% and deferoxamine is administered to reduce the resulting iron overload. Treatment with hydroxyurea to reduce the bone marrow porphyrin synthesis may be considered, especially after puberty when porphyrin production may increase (96). Splenectomy has substantially reduced transfusion requirements in some patients. Oral charcoal has increased fecal loss of porphyrins with milder disease, but seems less successful in more severe cases (97). Hemin therapy, which is effective for the treatment of the acute hepatic porphyrias, may be somewhat effective in CEP

but has not been extensively studied. Chloroquine has not been beneficial.

**99.4.4.5.2 Bone Marrow Transplantation.** Bone marrow transplantation (BMT) has proved curative for patients with CEP. To date, nine transplanted patients have been reported, and when successful, BMT has resulted in marked reduction in porphyrin levels and photosensitivity (for reviews, see (98,99)). The source of the hematopoietic stem cells has included bone marrow or umbilical cord blood from histocompatible sibs as well as from unrelated HLA-matched marrow.

**99.4.4.5.3 Experimental Gene Therapy.** The success of BMT provides the rationale for hematopoietic stem cell gene therapy. The stable transduction of the patient's own stem cells with vectors containing the URO-synthase cDNA would abrogate the need for HLA-identical donors and the risk of rejection. Various retroviral and lentiviral vectors expressing human URO-synthase have been used to transduce a variety of cell types including mononuclear cells derived from the bone marrow of normal and CEP subjects (100–106). Better transduction efficiencies were obtained with the lentiviral vectors than the retroviral vectors and all transduced cell types had increased URO-synthase activity and suppression of porphyrin accumulation. These studies are encouraging; however, in vivo efficacy of individual vector constructs may not be predictable from these in vitro experiments, and animal studies are needed. Such in vivo experiments could determine whether transduction of hematopoietic stem cells can be efficient enough to minimize the proportion of nontransduced progenitors capable of producing toxic quantities of porphyrins in their descendants.

## 99.4.5 Porphyrria Cutanea Tarda

Porphyrria cutanea tarda (PCT) is caused by reduced activity of URO-decarboxylase, the fifth enzyme in the heme biosynthetic pathway. PCT is unique among the porphyrias as this cutaneous and biochemical phenotype results from an acquired, liver-specific enzyme inhibition in both sporadic (type I) and familial (types II and III) forms (1,34,107). PCT is the most common porphyria and has an estimated frequency of 1 per 25,000, of which ~80% have type I disease (34,107). This porphyria can also result from exposure to certain polyhalogenated aromatic hydrocarbons. The most notable occurrence of environmentally induced PCT was an outbreak in Turkey in the 1950s, caused by the ingestion of wheat treated with the fungicide hexachlorobenzene (HCB).

### 99.4.5.1 Biochemical Aspects.

**99.4.5.1.1 Types I–III PCT Are Clinically Very Similar.** The enzymatic activity of hepatic URO-decarboxylase must be decreased by ~75% before porphyrins accumulate and clinical symptoms occur (34,107). However, the amount of hepatic URO-decarboxylase enzyme protein is not decreased below

its genetically determined level but is inhibited by a substance, not yet characterized, derived from a heme pathway intermediate (107). Production of the URO-decarboxylase inhibitor is iron-dependent. The multiple factors that can precipitate types I–III PCT act mostly be increasing hepatic iron content or oxidative stress (see later discussion). The genetically determined level of URO-decarboxylase in type II PCT is half-normal in all tissues, and the disease becomes manifested only when the hepatic enzyme becomes further reduced.

**99.4.5.1.2 Type I Porphyrria Cutanea Tarda.** In type I PCT, URO-decarboxylase activity is deficient in the liver and is normal in all other tissues such as erythrocytes. No URO-decarboxylase mutations have been identified in type I PCT. Moreover, there are no tissue-specific isoenzymes of URO-decarboxylase, and therefore, a mutation of the gene for this enzyme is unlikely to lead to a tissue-specific enzymatic deficiency. The tissue-specific enzymatic deficiency in type I PCT appears to be acquired because the amount of hepatic URO-decarboxylase protein, as measured immunochemically, is normal, suggesting that the enzyme has been inhibited, and with phlebotomy the enzyme activity gradually increases and both catalytic and specific activity may return to normal (108). URO-decarboxylase activity is not directly inhibited by iron. Considerable evidence suggests that type I PCT is caused by inhibition or inactivation of structurally normal URO-decarboxylase by a liver-specific, iron-dependent process that promotes the oxidation of uroporphyrinogen to uroporphyrin and a product that inhibits URO-decarboxylase. Efforts to isolate and characterize this inhibitor are currently in progress using laboratory models (107).

**99.4.5.1.3 Type II Porphyrria Cutanea Tarda.** In type II or familial PCT, the genetically determined level of URO-decarboxylase activity in all tissues is half-normal due to the autosomal dominant inheritance of a URO-decarboxylase mutation. The half-normal amount of enzymatic activity is the product of the normal URO-decarboxylase allele. Half-normal enzyme protein and activity is demonstrated in nonhepatic tissues such as erythrocytes and cultured skin fibroblasts in clinically affected individuals and in family members with latent disease. However, manifest type II PCT develops only when hepatic URO-decarboxylase becomes reduced considerably below the inherited enzyme level, and to levels of activity corresponding to type I PCT (107). The amount of hepatic enzyme protein remains half-normal in type II PCT.

URO-decarboxylase is not a rate-limiting enzyme for heme biosynthesis, and therefore most type II heterozygotes do not develop PCT unless precipitating factors are present (see later discussion) (107,109).

**99.4.5.1.4 Type III Porphyrria Cutanea Tarda.** Type III PCT is rare and is presumed to be inherited because more than one family member is affected. However, it resembles type I in that URO-decarboxylase

activity is normal in extrahepatic tissues such as erythrocytes and URO-decarboxylase mutations have not been identified (108). Therefore, the genetic basis for this type of PCT is not yet understood, and it is not readily differentiated from type I.

#### 99.4.5.1.5 *Hepatoerythropoietic Porphyrria.*

Hepatoerythropoietic porphyria (HEP) is the homozygous dominant form of type II PCT. This disease is rare, as only about 30 cases from 24 families have been reported (110). The URO-decarboxylase mutations causing HEP often do not lead to complete loss of the enzyme activity, and some are CRIM-positive (29,111). The URO-decarboxylase activity in HEP patients has ranged from 3% to 28% of normal (29).

**99.4.5.2 Genetic and Molecular Aspects.** URO-decarboxylase gene mutations are found only in type II PCT, as well as HEP. However, in types I and III PCT, other genetic as well as environmental factors (see later discussion) appear to contribute to the reduction of hepatic URO-decarboxylase in liver that is necessary for development of the clinically manifested disease.

The half-normal activity of URO-decarboxylase in type II PCT is clearly inherited as an autosomal dominant trait. Over 100 mutations in the URO-decarboxylase gene have been identified, including over 50 mutations underlying type II PCT, and ten different missense mutations causing HEP (Human Gene Mutation Database; [www.hgmd.org](http://www.hgmd.org)) (6). The ten mutations in the URO-decarboxylase gene identified in HEP include five such as G281E (112) that also have been found in type II PCT (29,31,110,113–116). HEP patients are either homoallelic or heteroallelic for the URO-decarboxylase mutations.

Of the URO-decarboxylase mutations listed in the Human Gene Mutation Database (6), 57.4% are missense, 0.7% nonsense, and 13.1% are splice-site mutations. Most URO-decarboxylase mutations have been identified in only one or two families. Exceptions include mutations g10insA (found in six Argentinean families) (111), G281E (found in 14 unrelated Spanish families) (112), and IVS6+1 (found in 6 unrelated families).

Type III PCT has been studied in four Spanish families, in which at least two relatives had clinical manifestations of PCT with decreased URO-decarboxylase activity in liver but normal levels in erythrocytes and other tissues. To date, no mutations of the URO-decarboxylase locus have been detected in type III PCT.

**99.4.5.3 Precipitating Factors.** A number of inherited and environmental factors contribute to the profound inhibition of hepatic URO-decarboxylase activity and the development of clinically manifested PCT. In type II PCT, the inheritance of a heterozygous URO-decarboxylase mutation predisposes to the disease because the amount of enzyme is half-normal initially, and less inhibitor is required to develop overt PCT (107). Other inherited susceptibility factors include HFE mutations (C282Y and H63D) that increase iron retention, and possibly

polymorphisms of cytochrome P450 enzymes (117). Environmental and infectious factors include excess alcohol consumption, hepatitis C virus infection, HIV infection, estrogen use, smoking, decreased levels of antioxidants such as vitamins E and C, and carotenoids (3,107,108,118). These appear to contribute to development of PCT by increasing oxidative stress in hepatocytes and the production of an inhibitor of URO-decarboxylase. Multiple factors are present and may act in an additive fashion in the individual PCT patient (119). A study of 84 Swedish patients with PCT found that 23% of the patients had Type II PCT and 57% had hemochromatosis mutations, 14% of whom were homozygous for the C282Y mutation. Other risk factors included alcohol abuse (38% of males), estrogen treatment (55% of females), and antihepatitis C virus (29% of males) (120).

Mutations in the hemochromatosis (HFE) gene may result in elevated tissue iron levels and therefore predispose to PCT. There are two common mutations causing hemochromatosis: the C282Y mutation causes hemochromatosis in homozygotes in northern Europeans and their descendants, and the H63D mutation, which is more common in southern Europe. One in ten normal individuals is a carrier of a HFE gene mutation and an increased frequency occurs in both sporadic and familial PCT patients (107,108,121). In American PCT patients, 63% to 73% had HFE mutations (119,122,123); in one series, 17 of 87 (19%) PCT patients were homozygous for C282Y compared with zero for the 56 controls (123). Among English PCT patients, 17% were found to be homozygous for the C282Y mutation and 20% were heterozygous (124). A review of eight studies (121) found a mutant hemochromatosis allele in 17% to 47% of patients with sporadic or familial PCT suggesting that the HFE gene is an important predispositional modifier gene for the clinical expression of PCT (121).

**99.4.5.4 Porphyrria Cutanea Tarda due to Halogenated Hydrocarbons.** In 1955 to 1958, an extensive outbreak of PCT occurred in eastern Turkey as a result of the ingestion of wheat treated with the fungicide HCB (1,108). Feeding of HCB to animals was subsequently shown to decrease hepatic URO-decarboxylase activity and to produce a porphyria biochemically similar to human PCT. Smaller case clusters have also been reported after exposure to other chemicals, including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD, dioxin) (108).

**99.4.5.5 Clinical Manifestations.** Skin lesions consist of fluid-filled vesicles and bullae on sun-exposed areas such as the dorsa of the hands and feet, the face, forearms, and legs. These may rupture, form crusted lesions, and heal slowly with residual scarring. Secondary infection may occur. Sun-exposed skin becomes friable, and minor trauma may precede the formation of bullae or may cause denudation of the skin. Small white plaques, termed milia, may precede or follow vesicle formation. Other cutaneous manifestations include hypertrichosis

and hyperpigmentation, especially of the face, which can present in the absence of vesicles. Thickening, scarring, and calcification of affected areas of skin are sometimes striking and has been termed pseudoscleroderma because it resembles the cutaneous changes of systemic sclerosis. The skin lesions in PCT are generally indistinguishable from those in VP and HCP.

PCT is commonly associated with evidence of chronic liver disease and sometimes with cirrhosis. Patients with PCT are also at risk to develop hepatocellular carcinoma; in several series, the incidence has ranged from 4% to 47%. These tumors appear as a complication of PCT and do not themselves contain or produce porphyrins in large amounts. They may result from longstanding liver damage in PCT, hemosiderosis, coexistent chronic hepatitis C infection, exposure to halogenated chemicals that are also carcinogenic, or to the effects of porphyrin deposition in the liver. PCT associated with advanced renal disease is often more severe and intractable than PCT occurring in its absence (1).

HEP resembles CEP clinically and usually presents in infancy or childhood with onset of blistering skin lesions, hypertrichosis, scarring, and red urine. HEP is genetically heterogeneous, and unusually mild cases have been described (125). Two mild cases of HEP with only minor scarring have recently been described in two unrelated patients, one in a 5-year-old boy and the other in a 38-year-old man (110,126). Interestingly, both patients were homoallelic for the same mutation F46L, which resulted in less than 10% of normal URO-decarboxylase activity in these patients.

**99.4.5.6 Laboratory Evaluation.** PCT is strongly suggested by the characteristic skin lesions in sun-exposed areas, especially on the backs of the hands. However, similar skin blistering is seen with other cutaneous porphyrias, with the exception of EPP. The most useful initial diagnostic test is a total plasma porphyrin determination. A normal plasma porphyrin level excludes PCT, whereas a high level with a fluorescence emission maximum at neutral pH near 619 nm excludes VP and is highly suggestive of PCT (108). Measurements of urinary and fecal porphyrins provide confirmation of PCT. URO-decarboxylase activity can be measured in erythrocytes and lymphoblasts (89) and can be used to distinguish Types I and II since Type 1 PCT patients will have normal levels of erythrocyte URO-decarboxylase, while Type II PCT patients will have ~50% of normal levels (15). Molecular analysis more reliably diagnoses type II patients by identifying the underlying URO-decarboxylase gene mutations (127).

Porphyrins are increased in the liver, plasma, urine, and stool in PCT (63). A slight increase in ALA is noted in some patients, but PBG excretion is normal. Urinary porphyrins consist mostly of uroporphyrin and 7-carboxyl porphyrin, with lesser amounts of coproporphyrin and 5- and 6-carboxyl porphyrins. The excess urinary uroporphyrin in PCT is predominantly

isomer I; 7- and 6-carboxyl porphyrins are mostly isomer III; and 5-carboxyl porphyrin and coproporphyrin are approximately equal mixtures of isomers I and III.

The finding of increased isocoproporphyrins, most readily demonstrated in feces, is diagnostic for a deficiency of URO-decarboxylase (34). These unusual 4-carboxyl porphyrins are produced when hepatic URO-decarboxylase is deficient, because 5-carboxyl porphyrinogen III, which accumulates in PCT, can be metabolized by COPRO-oxidase to yield dehydroisocoproporphyrinogen. This porphyrinogen is excreted in bile and undergoes auto-oxidation and side-chain modification by bacterial enzymes in the intestine to give isocoproporphyrin and deethylisocoproporphyrin, the major representatives of the isocoproporphyrin series in the feces of PCT patients. Increased liver porphyrins are composed mostly of uroporphyrin and 7-carboxyl porphyrin.

The biochemical findings in HEP are similar to those in other forms of PCT. In addition, the concentration of protoporphyrin in erythrocytes is increased and is predominantly zinc protoporphyrin.

**99.4.5.7 Therapy.** The diagnosis of PCT should be firmly established by biochemical investigations before treatment is initiated, because VP and HCP can produce similar cutaneous lesions but are unresponsive to measures that are highly effective in PCT. Imaging studies are advisable to exclude complicating hepatocellular carcinoma and to serve as a baseline for follow-up. Testing for known precipitating factors is recommended to include hepatitis C and HIV infections. Patients should abstain from alcohol, estrogens, iron supplements, or other exogenous agents that may exacerbate the disease. Drugs such as barbiturates, phenytoin, and sulfonamides that are harmful to patients with acute porphyrias are seldom reported to contribute to the clinical expression of PCT, but should be avoided as a precaution.

Standard therapy consists of repeated phlebotomy, which can produce remission in almost all patients (1). The aim is to gradually reduce excess hepatic iron by removing about 450 mL of blood at intervals of 1 to 2 weeks until the serum ferritin reaches the lower limits of normal (108). Plasma (or serum) porphyrin levels decrease in parallel and become normal within 1 to 2 months after the target ferritin concentration is achieved. Hemoglobin or hematocrit levels should be followed closely to prevent the development of symptomatic anemia. Continued phlebotomies are seldom needed even if ferritin levels later return to normal. However, it is advisable to follow porphyrin levels and reinstitute phlebotomies if porphyrin levels begin to rise. Even cutaneous scarring and pseudoscleroderma can improve with phlebotomy and serum markers for the liver cell function to normalize (108). Recombinant erythropoietin is an effective treatment and can support phlebotomy therapy when PCT is associated with end-stage renal disease (1).

Small doses of chloroquine (125 mg twice weekly) or hydroxychloroquine (100 mg twice weekly) are also

effective in producing remissions of PCT (127). These drugs promote excretion of accumulated porphyrins in the liver in PCT, possibly by complexing with porphyrins. However, the standard antimalarial doses of these drugs may induce acute hepatic damage, nausea, vomiting and fever, and elevated urinary and plasma porphyrin levels due to the release of large amounts of stored porphyrins from the liver (1). There may be a transient increase in photosensitivity. Such side effects are minimal or absent with much lower doses. This treatment is sometimes combined with repeated phlebotomy (108). Prospective study comparing these two forms of therapy is lacking.

### 99.4.6 Hereditary Coproporphyria

Hereditary coproporphyria (HCP) is an acute hepatic porphyria and results from the deficient activity of COPRO-oxidase, the sixth enzyme in the heme biosynthetic pathway. HCP is inherited as an autosomal dominant trait due to COPRO-oxidase mutations, whose clinical expression is influenced by ecogenic and metabolic factors. This condition is less frequent than AIP or VP (40). Clinical symptoms rarely occur before puberty and are very similar to AIP with the exception of photosensitivity, which can develop in HCP patients but much more rarely than in VP (1). Certain mutations in the COPRO-oxidase gene, such as K404E, when present in either the homozygous or compound heterozygous states produce a biochemical variant called harderoporphyria, characterized by increased fecal levels of a tricarboxylic porphyrin, harderoporphyrin (41,129). Cases of homozygous HCP have also been reported (42,43).

**99.4.6.1 Biochemical Aspects.** The activity of the mitochondrial enzyme COPRO-oxidase is about 50% of normal in cultured fibroblasts, circulating lymphocytes, and leukocytes from HCP heterozygotes. In one case of homozygous HCP, the residual COPRO-oxidase activity (approximately 2% of normal) had a normal  $K_m$  value. By contrast, in three cases in a family with harderoporphyria, the mutant enzyme exhibited increased thermostability and reduced affinity for both harderoporphyrinogen and coproporphyrinogen III, which is consistent with a structurally altered enzyme.

**99.4.6.2 Molecular Aspects.** Over 40 mutations in the COPRO-oxidase gene are listed in the Human Gene Mutation Database, including missense, nonsense, splice-site, and small insertion or deletion mutations (Human Gene Mutation Database; [www.hgmd.org](http://www.hgmd.org)) (6,130). Most have been identified in only one family (40). In a study of 17 unrelated British HCP patients, only one mutation, 1277G→A, which causes exon 6 skipping was found in more than one patient (131). No genotype–phenotype correlations have been observed in HCP (131). Five single nucleotide polymorphisms were identified in the COPRO-oxidase gene, but none appear to play a major role in clinical expression of HCP (132).

Studies of the human COPRO-oxidase crystal structure and a hydrophobic cluster analysis method indicated that only missense mutations in amino acids positions 400–404 in exon 6 resulted in harderoporphyria. In fact, mutation K404E is found either homoallelic or heteroallelic in all patients with harderoporphyria studied, to date. The amino acids in this region appear to be involved in retaining harderoporphyrinogen for the second decarboxylation step whereas mutations in these amino acids lead to the release of the porphyrinogen intermediate (39,41).

**99.4.6.3 Clinical Manifestations.** The neurovisceral symptoms of HCP are identical to those of AIP; however, the disease is probably less severe than AIP, and only a few patients have been reported to die from respiratory paralysis. Photosensitivity similar to that in PCT and VP sometimes occurs. In one series of 50 patients, the most common clinical manifestations were abdominal pain (80%), vomiting (34%), skin lesions (29%), neuropathic involvement (23%), psychiatric symptoms (23%), and constipation (20%) (40). In a study of 53 German HCP patients during acute manifestations, 89% had abdominal pain, 33% had neurologic symptoms, 28% had psychiatric symptoms, and 25% had cardiovascular symptoms, while only skin photosensitivity was observed in only 5% (114). In 69% of these patients, the abdominal pain occurred without other neurologic manifestations, while 27% of the patients had both abdominal and other neurologic symptoms; 4% had only neurologic symptoms (114). HCP can be exacerbated by many of the same factors that cause attacks in AIP, including drugs such as barbiturates and endogenous or exogenous steroid hormones. The disease is latent before puberty, and symptoms are more common in adult women than in men. Hepatitis and other superimposed liver diseases in an HCP patient can increase porphyrin retention and photosensitivity.

Patients with homozygous HCP, including some with harderoporphyria, developed symptoms in early childhood. Manifestations have included jaundice, severe hemolytic anemia with splenomegaly, and compensatory hyperactive bone marrow (43,133).

**99.4.6.4 Laboratory Evaluation.** A common and characteristic biochemical change in HCP is a large, isolated increase in fecal coproporphyrin, predominantly isomer III (40). Feces of symptomatic heterozygotes have a 10-fold to 200-fold increase in coproporphyrins and little or no increase in protoporphyrin. An increase in the ratio of coproporphyrin III to coproporphyrin I in feces is useful for diagnosis of both active and latent HCP. Increased urinary excretion of ALA, PBG, and total porphyrins (mostly uroporphyrin III and coproporphyrin III) is observed during acute attacks (114).

With resolution of symptoms, ALA and PBG levels revert to normal more readily in HCP (and VP) than in AIP, and HCP patients in nonacute stages may show only increases of urinary and fecal porphyrins. For

example, in a series of 53 German HCP patients, the average total urinary porphyrins during acute phases was 29,905 nmol/24 hr (6 patients) and around 1100 nmol/24 hr during subclinical and latent phases (average of 47 patients); normal levels were <224 nmol/24 hr (113). Total fecal porphyrins were 5508 nmol/g dry weight at active stages of HCP, compared with 1730 and 694 nmol/g dry weight (normal <224 nmol/g dry weight) in subclinical and latent phases, respectively. However, the percentage of the fecal coproporphyrin III isomer was still elevated in the patients in the subclinical and latent phases (114).

Porphyrin excretion patterns in homozygous HCP resemble those observed in heterozygotes but reflect a more profound enzymatic deficiency. Harderoporphyria is characterized by a marked increase in fecal excretion of harderoporphyrin as well as coproporphyrin. In one patient with harderoporphyria, 90% of the porphyrins in his feces were in the form of harderoporphyrin (129).

COPRO-oxidase activity can be measured in mononuclear cells (134). Individuals with a mutation in one of their COPRO-oxidase alleles have about 50% of normal activity in mononuclear cells. For screening family members, measurement of fecal porphyrins may be useful, especially if the ratio of coproporphyrin isomers I and III is determined; however, asymptomatic adults and children with the enzymatic deficiency may not excrete excess porphyrins.

**99.4.6.5 Therapy.** Acute attacks of HCP are treated in the same manner as in AIP (2). Hemin (lyophilized hydroxyheme or heme arginate) therapy is helpful in treating acute attacks of HCP (40). Cholestyramine may be of some value for photosensitivity occurring with liver dysfunction, but phlebotomy and chloroquine are not effective.

## 99.4.7 Variegate Porphyrria

VP is an autosomal dominant hepatic porphyria resulting from the deficient activity of PROTO-oxidase, the seventh enzyme in the heme biosynthetic pathway. The disorder is described as variegate because it can present with neurologic manifestations, photosensitivity, or both. The clinical penetrance of VP in adults is estimated at ~40% (135–137). In most countries, VP is less common than AIP, with the notable exception of South Africa, where 3 of every 1000 white persons have inherited VP. This high prevalence is due to a founder effect from a Dutch couple who immigrated to South Africa in 1688, one of whom carried a specific PROTO-oxidase mutation (133). A number of cases of homozygous dominant VP have also been described (49,50,138–141).

**99.4.7.1 Biochemical Aspects.** PROTO-oxidase activity is approximately half-normal in cultured skin fibroblasts and lymphocytes from VP patients. Because PROTO-oxidase is a mitochondrial enzyme, it is not present in mature erythrocytes. Assays for

PROTO-oxidase in lymphocytes or cultured cells are difficult and are not widely available for diagnosis and family screening (136).

Protoporphyrinogen IX, the substrate for PROTO-oxidase, accumulates in patients with VP and undergoes auto-oxidation to protoporphyrin IX, which is characteristically increased in VP. A close functional association between PROTO-oxidase in the inner mitochondrial membrane and COPRO-oxidase in the intermembrane space may relate to the excess excretion of both protoporphyrin IX and coproporphyrin III in this disease.

**99.4.7.2 Molecular Aspects.** Around 150 mutations in the PROTO-oxidase gene have been identified in patients with VP including missense, nonsense, splice site, and small deletions and insertions (Human Gene Mutation Database; [www.hgmd.org](http://www.hgmd.org)) (6,136). The missense mutation, R59W, is the common mutation in most South Africans with VP of Dutch descent (133). In 108 unrelated English and French VP patients, 66 mutations were identified; most were found in only one or two unrelated families, but five (L15F, E198X, L295P, 1082insC, and Q435X) had frequencies of 7% to 12% (142). No genotype/phenotype correlations were identified. In 21 Finnish VP families, the common missense mutation R152C was identified in 11 (52%), while the missense mutation I12T was found in two large families (9.5%) (137). Of interest, none of the patients with the I12T mutation had photosensitivity, only one had an acute attack, and all had lower levels of porphyrins than patients with mutation R152C (137). Mutations have also been identified in patients with the rarer homozygous dominant form of VP (48,49,138–141). Most have some residual enzymatic activity, allowing for synthesis of heme in amounts sufficient for many essential hemoproteins.

**99.4.7.3 Clinical Manifestations.** Clinical expression of VP before puberty is rare; the disease may even present late in life (143). VP can present with skin photosensitivity, acute neurovisceral crises, or both (47). In two large studies of VP patients from Europe and South Africa, 59% had only skin lesions, 20% had only acute attacks, and 22% had both (142). Among Finnish VP patients, the frequency of skin symptoms was 40% and acute attacks 27% (137). Interestingly, the proportion of Finnish patients with acute attacks decreased from 38% to 14% among patients diagnosed before and after 1980, while the proportion with skin symptoms remained similar. The reasons for the decline in symptoms are unclear (137). A similar decline in the frequency of acute attacks, from 38% before 1980 to 4% in 2004, was observed among South African VP patients, presumably due to increased detection and counseling of heterozygotes to avoid use of acute attack-inducing drugs, steroids, and dieting (135).

The neurovisceral manifestations of abdominal pain, vomiting, constipation, hypertension and tachycardia, and peripheral neuropathy are indistinguishable from those of AIP and HCP. Skin manifestations are very

similar to those of PCT and HCP, are usually of longer duration, and may occur apart from the neurovisceral symptoms. Photosensitivity is more common than in HCP. Drugs, steroids, and nutritional factors that are detrimental in AIP can also provoke exacerbations of VP (1,2). Photosensitivity may be less commonly associated with VP in more northern countries, where sunlight is less intense (136).

Patients with homozygous dominant VP have the early onset of symptoms, severe photosensitivity, absence of acute attacks, and elevated erythrocyte zinc protoporphyrin levels (49). In some cases, neurologic symptoms and developmental disturbances, including growth retardation, were noted in infancy or childhood. One homozygous VP patient had severe photosensitivity and mild sensory neuropathy and over a 20-year period developed IgA nephropathy (48). The heterozygous parents of these patients had approximately half-normal enzyme activity as expected.

**99.4.7.4 Laboratory Evaluation.** Fecal protoporphyrin and coproporphyrin and urinary coproporphyrin are markedly increased in clinically expressed VP. Urinary and fecal coproporphyrin is mostly type III. Urinary ALA, PBG, and uroporphyrins are increased during acute attacks but may be normal or only slightly increased during remission. ALA and PBG may be less elevated and return to normal more rapidly in VP and HCP than in AIP. Plasma porphyrins, consisting in part of a dicarboxylate porphyrin tightly bound to plasma proteins, are increased in VP particularly when photosensitivity or other symptoms are present. The fluorescence emission spectrum of plasma porphyrins at neutral pH in VP is characteristic and can distinguish this disease from other types of porphyria, especially PCT: the emission maxima occurs at 626 nm in VP; 619 nm in PCT, CEP, HCP, and AIP; and 634 nm in EPP (63). This method of measuring plasma porphyrins is perhaps the most sensitive method of detecting latent cases of VP, other than measuring PROTO-oxidase in lymphocytes or detecting a specific mutation by molecular methods. VP can be distinguished from HCP by fecal and plasma porphyrin analyses.

Assays for PROTO-oxidase are difficult, since the enzyme is not present in erythrocytes and are not widely available for diagnostic and family screening (63). Mutation analysis is preferred for confirming the diagnosis and detecting heterozygous relatives.

**99.4.7.5 Therapy.** Glucose, hemin, and other measures employed in AIP are recommended for the treatment of acute attacks of VP (2,47,136). Other therapies such as propranolol, D-penicillamine, hemodialysis, alkalization of urine, and b-carotene are of little or no benefit. Repeated venesections and chloroquine are not effective for skin manifestations in VP, even though these appear identical to those of PCT. Measures to protect the skin from sunlight with appropriate clothing and opaque sunscreen preparations are useful. Exposure to short-wavelength UV light, which does not excite

porphyrins, may provide some protection by increasing skin pigmentation.

### 99.4.8 Erythropoietic Protoporphyria

Erythropoietic protoporphyria (EPP) is due to the partially deficient activity of ferrochelatase, the last enzyme in the heme biosynthetic pathway (1,57). EPP also has been termed erythrohepatic protoporphyria and protoporphyria. EPP is the most common erythropoietic porphyria and, after PCT and AIP, is the third most common porphyria. EPP is an autosomal dominant disease in most affected families. However, many EPP patients had only 10% to 30% of normal ferrochelatase activity instead of the expected 50% of normal activity. Recently, it was shown that an intronic polymorphism in the wild-type allele reduces its expression, accounting for the lower level of enzymatic activity. EPP is therefore an autosomal dominant porphyria in which a low-expression polymorphism predisposes to clinical expression (penetrance) (134). The presence of the intronic polymorphism and the nature of the other mutation (e.g. null vs. missense) may be responsible in part for the penetrance and variable expressivity of this disease. In some families, the pattern of inheritance is autosomal recessive, with affected individuals inheriting a coding region mutation from each parent (144). Although the disease is most common in whites, it does occur in persons of other races, including blacks. The low expression polymorphism is found in ~10% of the normal white population and is also common in Asians but is rare in Africans (58). Recently, deletions in exon 11 of the ALAS2 gene have been described, which cause an X-linked protoporphyria (XLP) which is clinically indistinguishable from EPP. The deletion of the c-terminal amino acids of ALAS2 results in increased ALAS2 activity and the accumulation of protoporphyrin (145). XLP accounts for approximately 2% of cases with the EPP phenotype (146).

**99.4.8.1 Biochemical Aspects.** Partially deficient ferrochelatase has been documented in bone marrow, reticulocytes, liver, cultured fibroblasts, and blood or leukocytes from patients with EPP (1). The deficient enzyme activity becomes rate-limiting for protoporphyrin conversion to heme primarily in bone marrow reticulocytes. Ferrochelatase activity in tissue lysates of EPP patients has been reported to be as low as 10% to 30% of normal, which is much less than the 50% of normal activity that would be expected if EPP were inherited as an autosomal dominant enzymopathy. In a study of French and Swiss EPP patients, ferrochelatase activity ranged from 15% to 50% of normal (147). In a recently described variant form of EPP, ferrochelatase activity was normal, and an abnormality in iron delivery to the normal enzyme was postulated (148).

**99.4.8.2 Molecular Aspects.** To date, over 100 mutations in the ferrochelatase gene have been identified that cause EPP (Human Gene Mutation Database;

[www.hgmd.org](http://www.hgmd.org)) (6,147) including nonsense, missense, splice-site mutations, nonsense, and insertions/deletions or rearrangement mutations. Based on the type of mutation, about 75% of lesions result in an unstable or absent protein (null alleles). It has been suggested that there are genotype–phenotype correlations between mutations that result in unstable proteins (null) and liver complications in EPP patients. A study of 112 EPP patients with known ferrochelatase mutations found that all 18 EPP patients with severe liver complications had “null” alleles, while none of the 20 patients who had missense mutations developed liver complications (149). Another study of 31 EPP patients found that all 15 EPP patients with liver disease had null mutations (splicing, nonsense, or frameshift mutations), while 50% of the 16 patients who had only photosensitivity had missense mutations (150,151).

Mutation analysis of 105 English EPP patients identified three typical EPP patients with homozygous EPP, having two different mutations and one who was homoallelic for a missense mutation (152). The phenotypes of these homozygous EPP patients were very similar to EPP patients with one disabling mutation and the low expression intron 3 polymorphism, but their low ferrochelatase activity increased their risk for liver disease (152). In XLP, the erythrocyte protoporphyrin levels appear to be higher than other forms of EPP, and the proportions of free and zinc protoporphyrins are approximately equal.

**99.4.8.3 Genetic Aspects.** As noted previously, many EPP patients have about 20% to 30% of normal ferrochelatase activity rather than the 50% expected if the EPP was inherited as a simple autosomal dominant trait. Recent studies have shown that the presence of a polymorphism in intron 3 of the normal ferrochelatase allele affects the level of ferrochelatase activity and the severity of EPP. When the normal allele has a C at position -48 of intron 3, a cryptic acceptor splice site is activated, resulting in the insertion of 63 bp of the intron into the coding sequence (134). The IVS3-48C mRNA transcript contains a new stop codon and is rapidly degraded. The IVS3-48C polymorphism was present in ~10% of normal European individuals, 43% of normal Japanese, 31% of normal southeast Asians, and <1% of normal black West Africans (58,134,152). Transfection studies showed that the IVS3-48C construct produced ~40% aberrantly spliced mRNAs, while the common IVS3-48T construct produced only 20% aberrantly spliced mRNAs (134).

In studies of 40 unrelated European and 31 American symptomatic EPP patients, 95% (38 of 40) and 94% (29 of 31), respectively, had the IVS3-48C allele (132,150). Of note, none of 12 asymptomatic individuals with ferrochelatase mutations had the IVS3-48C allele (151). Additional studies of 113 overt French EPP patients and 61 asymptomatic carriers showed that none of the asymptomatic carriers had the IVS3-48C allele while 93 of 95 overt patients did (58). The EPP patients with the

IVS3-48C allele had lower levels of ferrochelatase activity than individuals with the IVS3-48T allele. These studies and others (150,153–155) indicate that symptomatic disease in most EPP patients is the result of a mutation in one ferrochelatase allele that alters markedly the structure, stability, and activity of the enzyme protein and a low expressing normal ferrochelatase allele, which is caused by the presence of the IVS3-48C polymorphism. Therefore, it appears that in most families the presence or absence of the IVS3-48C allele determines which individuals will be symptomatic.

In patients who do not have the IVS-48C polymorphism, it is possible that their reduced ferrochelatase activities result from the fact that the enzyme is a homodimer, and the dimerization of mutant and wild-type polypeptides may reduce the total activity. Recent studies of recombinant human wild-type and mutant ferrochelatase, expressed in *E. coli*, confirmed that ferrochelatase functions as a dimer and indicated that, for some mutations, the dimeric enzymes containing only mutant or mutant and wild-type heterodimers may be unstable or have markedly reduced activity (50,156).

Mouse models of EPP (157,158) may help further clarify the lower than expected ferrochelatase activity in EPP patients. In these models, the different genetic backgrounds or the absence of the heme-regulated eIF2a kinase (HRI) can effect the clinical severity of EPP (157,159). In XLP, to date, only two ALAS2 mutations, all deletions of 1 to 4 bases, have been described, which markedly increase ALAS2 activity (145).

**99.4.8.4 Etiology and Pathogenesis.** Porphyrins absorb light maximally at wavelengths near 400 nm (the Soret band) and enter an excited energy state that is manifested by fluorescence and, in the presence of molecular oxygen, by the formation of singlet oxygen and other oxygen species that can produce tissue damage. As might be expected, the skin is maximally sensitive to 400-nm light in EPP. Light-induced tissue damage may be accompanied by lipid peroxidation, oxidation of amino acids, and crosslinking of proteins in cell membranes. Histologic changes, predominantly in the upper dermis, may include amorphous material deposited around blood vessels and may resemble the findings in PCT. Immediate light-induced damage to capillary endothelial cells in the upper dermis has been described in EPP.

Circulating erythrocytes are an insufficient source for the excess protoporphyrin produced and excreted in EPP, and the presence of brightly fluorescent immature erythroid cells in the bone marrow of EPP patients presumably is a major source of the excess protoporphyrin (57). The liver also may be a source for some of the accumulated protoporphyrin (108); however, the relative contribution of hepatic and erythroid sources of the excess protoporphyrins is unclear. Studies in an EPP mouse model showed that bone marrow cells from a wild-type animal when transplanted into an irradiated EPP animal corrected the photosensitivity and fatal liver

disease, suggesting that the bone marrow was the major site for the excess protoporphyrins (160). In the reverse experiment, transplanting EPP bone marrow cells into irradiated normal mice resulted in protoporphyria (38% of erythrocytes contained fluorescent protoporphyrins), but not in liver disease, suggesting that the absence of ferrochelatase activity in the liver is a necessary component for development of EPP-associated liver disease (161). The normal recipients of EPP bone marrow cells also showed minimal skin photosensitivity despite high levels of plasma and erythrocyte protoporphyrins, suggesting that normal ferrochelatase activity in skin prevented photosensitivity (161).

Free protoporphyrin in EPP binds less readily to hemoglobin than does zinc protoporphyrin and diffuses more rapidly into the plasma. Moreover, UV light may cause free protoporphyrin to photodamage its hemoglobin-binding site and thus be released from the erythrocytes, even without disruption of the cell membrane. Protoporphyrin may then diffuse into the plasma, where it is bound to albumin. This light-mediated mechanism for the release of free protoporphyrin from hemoglobin in EPP may be important because binding of excess free protoporphyrin to hemoglobin is usually greater than binding to plasma proteins. Most of the protoporphyrin in erythrocytes is found in a small percentage of cells, and the rate of protoporphyrin leakage from these cells is proportional to their protoporphyrin concentration. The capacity of the liver to take up and excrete protoporphyrin into bile may also influence the flux of protoporphyrin from erythroid cells to the plasma.

In uncomplicated cases, hemolysis is uncommon or very mild. However, mild anemia with hypochromia and microcytosis or mild anemia with reticulocytosis is sometimes noted (144). Depletion of iron stores may be relatively common even in the absence of iron-deficiency anemia in EPP. Iron accumulation in erythroblasts and ring sideroblasts occur in some EPP patients.

Patients with EPP have high concentrations of protoporphyrin in bile and seem predisposed to develop gallstones that are fluorescent and composed at least in part of protoporphyrin. Protoporphyrin is cholestatic when infused intravenously in rodents. The potentially life-threatening hepatic complications of EPP are often preceded by increasing levels of erythrocyte and plasma protoporphyrin, abnormal liver function tests, and marked deposition of protoporphyrin in liver cells and bile canaliculi.

**99.4.8.5 Clinical Manifestations.** A major clinical feature of EPP is cutaneous photosensitivity, which usually begins in childhood. Photosensitivity is associated with substantial elevations in erythrocyte protoporphyrin and occurs only in patients with a genotype that results in ferrochelatase activity below ~35% of normal (3,108). Protoporphyrin levels remain quite constant over time, although cutaneous symptoms are generally more troublesome in the spring and summer when

sunlight exposure is greatest. Burning, itching, erythema, and swelling are the most common symptoms and can occur within minutes of sun exposure. Even brief exposure to the sun may result in intense skin pain lasting for hours, which has been described like “having a lighted match held against the skin or hot needles stuck into it” (108). Edema of the skin may be diffuse and resemble angioneurotic edema. Burning, itching, and intense pain can occur without obvious skin damage. Vesicles and bullae are absent or sparse. Epidermal intracellular vacuoles and interstitial edema are seen in fresh lesions, accompanied by acute inflammatory changes and extravasated red cells (57). Some residual scarring from vesicles or severe swelling may occur, but this is rarely severe or deforming. Pigment changes, friability, and hirsutism also are not characteristic of EPP. Thus, the cutaneous features of this disease are distinct from those of other cutaneous porphyrias. Also, in contrast to CEP, there is no discoloration or fluorescence of the teeth. It is also notable that neuropathic manifestations are not found in EPP, except rarely with advanced liver failure.

Although this is an erythropoietic porphyria, the hepatic complications that develop in a small percentage of patients (probably less than 5%) are most life threatening. Liver function is usually normal in this disease, but up to 20% of patients may have minor abnormalities of liver function. In XLP, about 17% of patients had overt liver disease, suggesting that the risk of liver disease may be higher with XLP than classic EPP (145). Rapidly progressive liver disease appears to be related to the cholestatic effects of protoporphyrin and is associated with increasing protoporphyrin levels due to impaired hepatobiliary excretion and increased photosensitivity (144). Splenic enlargement and hemolysis may be accompanying features. Upper abdominal pain may suggest biliary obstruction (57). Concurrent factors impairing liver function or the metabolism of protoporphyrin to heme, such as viral hepatitis, alcohol, iron deficiency, and fasting or oral contraceptive steroids, have played a role in some patients. An enterohepatic circulation of protoporphyrin may favor its retention in the liver, especially when liver function is impaired. Liver biopsies of EPP patients with severe liver disease contain dark brown pigment with a typical birefringence under polarized light. This pigment is protoporphyrin, which has been deposited in hepatocytes, macrophages, bile canaliculi, and small bile ducts. For a detailed discussion of the hepatic complications of EPP, see Cox (144) and Thunell and coworkers (162).

**99.4.8.6 Clinical and Laboratory Evaluation.** EPP should be suspected in individuals with intense skin pain after short exposure to the sun without blistering skin lesions (144). A lack of severe cutaneous signs distinguishes this disease from all other cutaneous porphyrias. Protoporphyrin concentrations are increased in the bone marrow, circulating erythrocytes, plasma, bile, and feces of EPP patients.

A substantial increase in erythrocyte protoporphyrin concentration, which is a readily obtained measurement, is essential for diagnosis of EPP. Erythrocytes also exhibit red fluorescence when studied by fluorescence microscopy at 620nm (163). However, an increased erythrocyte protoporphyrin concentration is not specific to EPP. Erythrocyte protoporphyrin concentrations are increased in other conditions such as lead poisoning, iron deficiency, anemia of chronic disease, and various hemolytic disorders, and also in all homozygous forms of porphyria and sometimes in acute porphyrias. However, the increased protoporphyrin in conditions other than EPP is in the form of zinc protoporphyrin, whereas in EPP it is free protoporphyrin (not complexed with zinc). Many assays for erythrocyte protoporphyrin or “free erythrocyte protoporphyrin” measure both the zinc-chelated and the free protoporphyrin. Free protoporphyrin is distinguished from zinc protoporphyrin by ethanol extraction or HPLC (144). In XLP, both free and zinc protoporphyrins are increased in equal proportions.

Plasma porphyrins may be less increased in EPP than in other porphyrias with cutaneous manifestations (1). Other heme pathway intermediates do not accumulate in EPP. Thus, urinary porphyrin and porphyrin precursor concentrations are generally normal. Fecal total porphyrins may be normal or somewhat elevated. Life-threatening hepatic complications of EPP are commonly preceded by increased photosensitivity and by increasing erythrocyte and plasma protoporphyrin levels. The ratio of erythrocyte to fecal protoporphyrin and the ratio of biliary protoporphyrin to biliary bile acids may also be observed to increase as liver failure develops. Ferrochelatase is a mitochondrial enzyme and can be measured in lymphocytes isolated from peripheral blood. As mentioned previously, EPP patients may have only around 20% to 30% of normal activity. Mutation analysis can be used to identify mutations and polymorphisms in the ferrochelatase gene.

A high prevalence of Vitamin D deficiency has been observed in EPP patients (164) and measurement of Vitamin D 25 OH levels would be recommended for monitoring these patients.

**99.4.8.7 Treatment.** Photosensitivity is managed by avoiding excessive sunlight and long-wave UV light. b-carotene was developed as a drug for treating EPP (162) and may improve tolerance to sunlight. Doses of 120 to 180mg daily in adults are usually required to maintain serum carotene levels in the recommended range of 600–800mg/dL. Improvement is noted 1–3 months after the initiation of treatment. With pure preparations of b-carotene, no side effects other than a mild and dose-related skin discoloration due to carotenemia have been noted. The mechanism of action may involve quenching of singlet oxygen or free radicals. The drug appears less effective in other forms of porphyria associated with photosensitivity, such as CEP and PCT. Dihydroxyacetone and lawsone (naphthoquinone),

which darken the skin when applied topically, partially block exposure of the dermis to light and are of some benefit in EPP. Cholestyramine, which may interrupt the enterohepatic circulation of protoporphyrin and promote its fecal excretion, has been reported to reduce liver protoporphyrin and improve cutaneous symptoms in some EPP patients. Increasing skin pigmentation by exposure to short-wave UV light may also offer some protection. Caloric restriction, drugs and hormone preparations that exacerbate acute porphyrias are often avoided in EPP, and iron deficiency should be corrected if present. Vitamin D should be supplemented if deficient.

Treatment of hepatic complications is difficult and must be individualized. Cholestyramine and other porphyrin absorbents, such as activated charcoal, should be considered. Oral bile acid supplementation has shown benefit in some animal models but has been little studied in EPP patients. Resolution of hepatic complications may also occur spontaneously, especially if another reversible cause of liver dysfunction, such as viral hepatitis or alcohol, is contributing. Splenectomy may be beneficial when EPP is complicated by hemolysis and splenomegaly. Other therapeutic options include transfusions and intravenous hemin to suppress erythroid and hepatic protoporphyrin production, as well as liver transplantation. However, liver disease may recur after transplantation (165).

### 99.4.9 Dual Porphyrrias

Patients with deficiencies of more than one heme biosynthetic enzyme are classified as having dual porphyria. For example, kindreds with individuals having both VP and familial PCT have been described. Patients with deficiencies of both HMB-synthase and URO-decarboxylase may develop symptoms of AIP, PCT, or both. COPRO-oxidase deficiency inherited from one parent and URO-synthase deficiency from both parents was found to cause severe porphyria in an infant. Coexistence of URO-synthase and URO-decarboxylase deficiencies has been described in a patient with features of an erythropoietic porphyria (166). Mutation analysis was not performed on these patients to confirm that the patient actually has mutations in two different genes. This is important, as shown by studies of a patient initially thought to have both VP and AIP but who was found to have a PROTO-oxidase mutation but no HMB-synthase mutation (167). A patient with both sporadic PCT and HCP due to an inherited COPRO-oxidase mutation was identified based on the urinary porphyrin pattern (168). Recently, ALA-dehydratase and COPRO-oxidase gene mutations were confirmed in one patient (169), and HMB-synthase and URO-decarboxylase gene mutations in another (170), as predicted by biochemical findings. These are the first two cases of dual porphyria where mutations in two different genes have been identified.

## ACKNOWLEDGMENTS

This was supported in part by grants from the National Institutes of Health (NIH) including research grants (5 R21 DK073093 and 5 R01 DK026824), a grant (1 U54 DK083909) for the Porphyrias Consortium of the NIH Rare Diseases Clinical Research Network (RDCRN), that includes funding and/or programmatic support from the NIH Office of Rare Disease

Research (ORDR), and a General Clinical Research Center grant (MO1-RR000073) and a Clinical and Translational Science Award (UL1 RR029876-01), both from the National Center for Research Resources, and by a grant from the US Food and Drug Administration Office of Orphan Product Development (R01FD002604).

### 100.1 INTRODUCTION

Copper is an essential dietary component, required in small amounts (1.5–3.0 mg/day) and distributed throughout the body (1–5). While the highest concentrations are in the liver, brain, heart, and kidneys, about 50% of total body copper is harbored in the large mass of muscle and bone. In humans, 30–60% of ingested copper is absorbed in the stomach and small intestine. The metal is then transported from the intestine to the blood, where copper binds to albumin at a specific site or to amino acids and is delivered to all tissues including liver. In the liver, copper is incorporated into the iron oxidase, ceruloplasmin, which is synthesized and metallated in the liver, and exported into plasma. Also in the liver, copper is excreted into the bile as amino acid and bile acid complexes, by way of a high-capacity excretory pathway in hepatocytes. This final sequence represents the major excretory pathway for copper, and the metal so processed is not available for resabsorption.

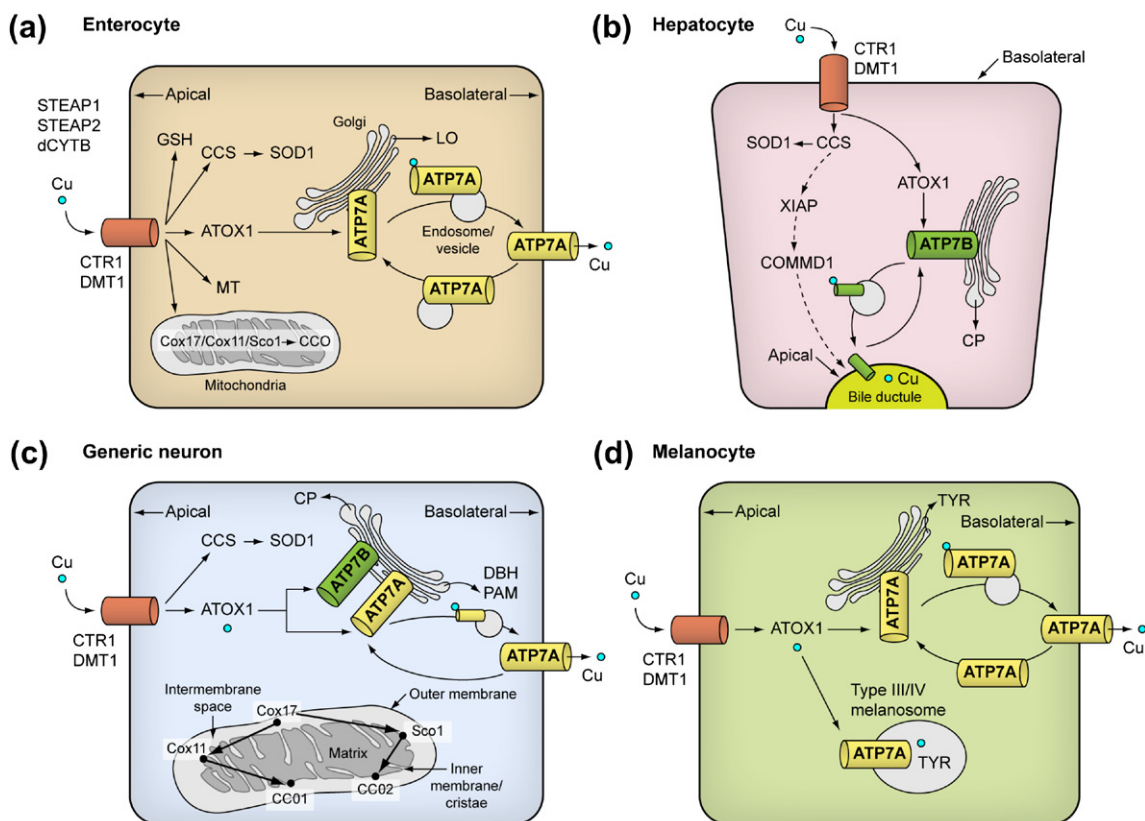

Copper transport and utilization in mammalian cells can be divided into three distinct and interrelated steps: copper uptake, copper excretion, and intracellular copper distribution and utilization (6,7). Intestinal absorption of copper across the apical membranes of enterocytes is mediated by the copper uptake proteins copper transporter 1 (CTR1) and divalent metal transporter 1 (DMT1) possibly in concert with the metalloredutases STEAP1, STEAP2, and dCYTB (Figure 100-1a). The roles of CTR2 (not shown) and DMT1 in this process are less certain. Within enterocytes, glutathione (GSH) and small proteins called metallothioneins (MTs) function in copper sequestration and storage. The copper chaperones CCS, ATOX1, Cox17, Cox11, and Sco1 ferry copper to specific proteins or organelles. As intracellular copper levels increase, ATP7A,

a copper-transporting ATPase, trafficks from the trans-Golgi network to the basolateral cell membrane and pumps copper into the bloodstream, entering the portal circulation.

Upon reaching the liver, the major organ of copper homeostasis, copper entering hepatocytes is directed toward one of several destinations (Figure 100-1b). Copper may be stored within the hepatocytes (bound to MTs), secreted back into the circulation (bound to ceruloplasmin), or excreted into the bile. The latter process is mediated by ATP7B, a copper transporter closely related to ATP7A, and may require interaction with the protein COMMD1. In neurons (Figure 100-1c) and other specialized cells (e.g. melanocytes, Figure 100-1d), other cuproenzymes (DBH, PAM, TYR) are efficiently metallated by the copper ATPase.

Since 90–95% of total plasma copper is bound to ceruloplasmin, and copper does not readily dissociate from ceruloplasmin, it was once hypothesized that copper entered peripheral cells following a ceruloplasmin-receptor interaction at cell surfaces. Since plasma copper also binds to albumin, alpha-2-macroglobulin, and amino acids such as histidine, these complexes were considered to be additional mediators of copper delivery to peripheral cells (8,9). However, individuals with the genetic disorders aceruloplasminemia (10), and analbuminemia (11), have normal copper status, indicating that neither ceruloplasmin nor albumin is essential for delivery of copper to mammalian cells. Table 100-1 provides detailed descriptions of proteins involved in human copper metabolism.

In all polarized cells, ATP7A and ATP7B reside in the *trans*-Golgi network and transport cytoplasmic copper to this compartment for incorporation into copper enzymes but relocate toward the plasma membrane to

**FIGURE 100-1** Cellular copper metabolism. (a) In enterocytes, copper (Cu<sup>+</sup>) uptake is mediated by CTR1, possibly in concert with the metalloregulators STEAP1, STEAP2 and dCYTB. The roles of CTR2 (not shown) and DMT1 in this process are less certain. Within enterocytes, GSH and MT function in copper sequestration and storage. The chaperones CCS, ATOX1, Cox17, Cox11 and Sco1 ferry copper to specific proteins or organelles. With an increase in copper levels, ATP7A traffics to the basolateral surface and pumps copper into the blood. (b) In hepatocytes, ATOX1 provides copper to ATP7B for metallation of CP and traffics to the apical membrane to pump copper into the bile, the body's major mechanism for copper removal. CCS has been proposed to deliver copper to XIAP, which may interact with COMMD1, a protein mutated in hepatic copper toxicosis of Bedlington terriers and which may modulate ATP7B activity. This putative pathway is denoted by dashed lines. (c) In neuronal cells, both ATP7A and ATP7B are expressed and required for maturation of CP, DBH and PAM. Details of CCO metallation are illustrated here. (d) In melanocytes, TYR acquires copper within melanosomes via ATP7A, which also localizes to the trans-Golgi. Abbreviations: ATOX1, copper transport protein ATOX1; ATP7A, copper-transporting ATPase 1; ATP7B, copper-transporting ATPase 2; CCS, copper chaperone for SOD1; CCO, cytochrome c oxidase; COMMD1, COMM domain-containing protein 1; COX11, cytochrome c oxidase assembly protein Cox11; Cox17, cytochrome c oxidase copper chaperone; CP, ceruloplasmin; CTR, copper transporter; DBH, dopamine-β-hydroxylase; dCYTB, cytochrome b reductase 1; DMT1, divalent metal transporter 1; GSH, glutathione; LO, lysyl oxidase; MT, metallothionein; PAM, peptidylglycine α-amidating monooxygenase; Sco1, protein SCO1 homolog; SOD1, superoxide dismutase; STEAP, six-transmembrane epithelial antigen of prostate; TYR, tyrosinase; XIAP, X-linked inhibitor of apoptosis.

mediate an exodus of copper from the cell in response to an increase in the intracellular concentration of this metal (12). ATP7A typically traffics to the basolateral membrane, while ATP7B moves toward the apical surface (13–16). The molecular domains responsible for the intracellular relocation and trafficking of ATP7A, along with their effects, are summarized in Table 100-2.

One might predict that mutations causing deficient function of copper chaperones would lead to mitochondrialopathies or to neurodevelopmental abnormalities with clinical and chemical evidence of copper deficiency. Mutations in the copper chaperone genes have not been associated with heritable disorders in humans, except for a single patient of consanguineous parentage homozygous for a loss-of-function missense mutation in CCS, associated with a complex clinical and biochemical phenotype (17).

Enzymes that utilize copper as a cofactor in functional catalytic reactions include the following: cytochrome c

oxidase (mitochondrial respiratory chain); superoxide dismutase-1 (free radical eradication); lysyl oxidase (rate-limiting collagen and elastin crosslinking reaction steps); tyrosinase (melanin formation); ceruloplasmin (iron oxidase, iron homeostasis); dopamine-β-hydroxylase (synthesis of catecholamines, neurologic development); and peptidylglycine α-amidating monooxygenase, responsible for chemical modifications of a significant fraction of neuropeptides (Table 100-1).

It should be clear from the foregoing that copper is an essential nutritional requirement for growth and development. However, at both organismic and cellular levels, extensive regulatory mechanisms exist to maintain a delicate balance (18) between necessity and toxicity. In a large measure, these homeostatic regulatory mechanisms are needed because the oxidative properties of copper are utilized in copper-dependent functions. Failure to maintain such a delicate balance can occur in

**TABLE 100-1 Proteins Important in Human Copper Metabolism**

Category	Name	Description
Copper import	CTR1	High-affinity copper uptake; localization at apical and basolateral plasma membranes and intracellular vesicles
	CTR2	Proposed low-affinity copper transporter; lacks methionine-rich domains present in CTR1
	DMT1	Facilitates divalent metal ( $\text{Fe}^{2+}$ , $\text{Cd}^{2+}$ , $\text{Co}^{2+}$ , $\text{Cu}^{2+}$ , $\text{Ni}^{2+}$ , $\text{Mn}^{2+}$ , $\text{Pb}^{2+}$ , $\text{Zn}^{2+}$ ) uptake via proton exchange
	STEAP	Reduces cupric ( $\text{Cu}^{2+}$ ) and ferric ( $\text{Fe}^{3+}$ ) ions in conjunction with cellular metal uptake
Copper export	ATP7A	P-type copper ATPase; mutated in Menkes disease, OHS and a distal motor neuropathy
	ATP7B	P-type copper ATPase highly expressed in hepatocytes; mutated in Wilson disease
	COMMD1	Required for hepatic copper excretion (is mutated in Bedlington terrier copper toxicosis); physically interacts with ATP7B
Copper chaperone	ATOX1	Cytosolic copper chaperone that ferries $\text{Cu}^+$ to ATP7A and ATP7B
	CCS	Cytosolic copper chaperone that ferries $\text{Cu}^+$ to SOD1 and XIAP
	COX17	Mitochondrial copper chaperone responsible for supplying copper ions, through the assistance of SCO1 or SCO2 and COX11, to cytochrome c oxidase, the terminal enzyme of the mitochondrial energy producing respiratory chain
	COX11	Accessory factor required to mediate copper transfer from COX17 to the $\text{Cu}_\text{B}$ site of cytochrome c oxidase subunit 1
	SCO1	Receives copper in transfer from COX17 en route to metallation of the $\text{Cu}_\text{A}$ site of CCO subunit 2
	SCO2	Partners with SCO1 in mammalian cells for delivery of copper to CCO
Storage and transfer	ALB	Albumin; a protein abundant in serum and cerebrospinal fluid; binds copper via a four-amino acid (DAHK) motif in amino-terminal region
	A2M	$\alpha_2$ -Macroglobulin or transcuprein; a major serum macroglobulin that also binds copper
	GSH	Glutathione; a sulfhydryl-containing tripeptide—abundant in the reducing environment of the cytosol—that binds and retains copper in the $1^+$ valence state
	MT	Metallothionein; a cysteine-rich metal-binding protein that sequesters excess intracellular copper
Copper enzyme	CP	Ceruloplasmin; a copper-containing serum ferroxidase needed to load ferric iron into transferrin
	HEPH	Hephaestin; a copper-containing transmembrane ferroxidase that exports iron from cells
Copper enzyme	SOD1	Superoxide dismutase; cytosolic antioxidant enzyme that catalyzes the conversion of superoxide to oxygen and hydrogen peroxide
	CCO	Cytochrome c oxidase; terminal enzyme of mitochondrial energy-producing respiratory chain
	DBH	Dopamine- $\beta$ -hydroxylase; key enzyme in catecholamine biosynthetic pathway; active in noradrenergic neurons
	PAM	Peptidylglycine- $\alpha$ -amidating monooxygenase; critical for amidation of numerous neuropeptides, which can enhance their bioactivity by several orders of magnitude.
	LO	Lysyl oxidase; oxidative deamination of lysine residues in collagen and elastin precursors needed for maturation of connective tissue
	ABP1	Diamine oxidase; a cuproenzyme required for degradation of histidine
	TYR	Tyrosinase; key enzyme in melanin biosynthetic pathway. Metallated in the Golgi compartment as well as in melanosomes
Regulator	XIAP	X-linked inhibitor of apoptosis; receives copper from CCS and, in turn, can regulate the metallochaperone via ubiquitination; also interacts with COMMD1; when not metallated, XIAP mediates degradation of COMMD1, reducing copper export

nutritional copper deficiency, caused by malnutrition, prolonged diarrhea in infants and children, and long-term parenteral alimentation without copper supplementation. The anemia, neutropenia, blood vessel fragility, skeletal defects, central nervous system dysfunction, and hypopigmentation of nutritional copper deficiency may be explained by functional deficiencies in the activities of the multiple cuproenzymes noted previously (19,20). If copper deficiency persists, patients may show decreased bone density and, in some cases, a peripheral neuropathy (21–28). In contrast, acquired acute copper poisoning manifests as nausea, vomiting, and diarrhea (29). Pathology includes ulceration of the intestinal mucosa, hepatic cell necrosis, jaundice, and hemoglobinuria. Toxicity of

copper excess may be ascribed to the inhibition of multiple enzyme systems, the mediation of free radical production, and the direct oxidation of cellular components (30,31).

Importantly, the symptoms of copper deficiency overlap with those of the genetic disorder, Menkes disease, in which cells and organs show a functional copper insufficiency, deficient copper utilization, or both. In contrast, the symptoms of copper poisoning mirror the manifestations of the copper overload observed in the genetic disorder, Wilson disease. Accordingly, the elucidation of the pathogenesis of Menkes disease and Wilson disease has directly impacted our understanding of the biology of mammalian copper transport and utilization.

**TABLE 100-2 ATP7A Molecular Traffic Signals and Effects**

1.	38 amino acid segment in 3rd transmembrane domain – Movement from endoplasmic reticulum to <i>trans</i> -Golgi
2.	N-terminal Cu-binding motifs – Movement from <i>trans</i> -Golgi network to plasma membrane
3.	C-terminal di-leucine motif at positions 1487–1488 – Endosomal retrieval of ATP7A from the plasma membrane
4.	C-terminal PDZ motif (DTAL) at positions 1497–1500 – Basolateral (instead of apical) localization in polarized cells
5.	CPC motif in TM6 at positions 1000–1002 – Cu-induced relocalization from post-Golgi vesicles to PM
6.	Phosphorylation motif (DKTG) at positions 1044–1047 – Cu-induced relocalization from post-Golgi vesicles to PM
7.	Phosphatase motif (LITGEA) at positions 873–878 – Endosomal retrieval of ATP7A from the plasma membrane

In turn, the resultant expansion in our knowledge of copper biology has led to an improved understanding of disease mechanisms and given investigators the tools to uncover other human genetic disorders of copper transport. In Menkes disease and Wilson disease, we have truly proceeded “from patients to gene,” and back to patients (32).

## 100.2 MENKES DISEASE

Menkes disease is an X-linked recessive neurodegenerative and connective tissue disorder, in which defective cellular copper export causes trapping of copper in some tissues (notably intestinal mucosa and kidney), leading to failure of copper delivery to other tissues (such as the central nervous system), and resultant systemic copper insufficiency. The disease was described by John Menkes nearly 50 years ago (33), and the X-linkage and syndromic nature of the disorder were noted in that early work. The disorder was subsequently shown by Danks and coworkers to involve defective copper homeostasis (34), with a copper deficiency phenotype due to failure of copper absorption from the small intestine. The disorder was later shown to be due to mutations in a gene encoding a copper-transporting P-type ATPase, ATP7A, or MNK (35–37). Subsequent experimental work showed that the MNK transporter functions in intracellular translocation and cellular efflux of copper (38–40). The identification of the X-chromosomal Menkes gene quickly led to the identification and cloning of a homologous autosomal gene, ATP7B, which was shown to be the gene for Wilson disease (41–43). Finally, the isolation of the Menkes- and Wilson disease genes led to the confirmation that mutations in homologs of the human genes are the proximate causes of the phenotypes of animal models for these disorders: the mottled mouse series for Menkes disease, and the toxic milk mouse, and LEC rat for Wilson disease (44). Experiments in these true animal analogs have considerably improved our understanding of the physiologic

role of the transporters (40,45) and the pathophysiology of the human diseases (46).

### 100.2.1 Clinical Features

Classical and lethal Menkes disease, with an estimated incidence of 1 in 90,000 to 1 in 254,000 live births (47), presents in the newborn period or in early infancy with nonspecific neurologic manifestations. Hypothermia, lethargy, poor feeding and failure to thrive, and myoclonic seizures are common (16,48). There are various degrees of spasticity, with limited spontaneous movement. At least two severe cases have been described with neonatal cutis laxa (49,50). Approximately 50% of patients show severe ocular manifestations, including poor visual acuity, myopia, strabismus, and peripheral retinal hypopigmentation (51). Development is generally severely delayed, and death occurs in early childhood.

There is a facial resemblance among patients, due in part to the distinct craniofacial configuration, and in part to the hair abnormalities. The face is described as “pudgy” or “cherubic” (Figure 100-2). Based on the steely, depigmented hair, the disorder was used to be known as “kinky hair disease” or “steely hair disease.” The hair is fragile and frequently broken; pili torti is seen on microscopic examination (Figure 100-3). Seborrheic dermatitis can be a persistent skin manifestation.

Central nervous system features include demyelination, reactive gliosis, and neuron loss in the cerebral hemispheres, the cerebellum, and the spinocerebellar tract (52). However, central nervous system manifestations in Menkes disease include not only neurodegenerative changes of a diffuse and unspecified nature but also selective defects that may be of developmental origin. These include abnormal dendritic arborization of pyramidal neurons; primary cellular degeneration in the thalamus; and reduced number and abnormal dendritic arborization of Purkinje cells (52). The developmental nature of these defects and early onset of neurological disease suggest that Menkes disease could have prenatal effects.

Radiographic studies are helpful in the diagnosis of Menkes disease and in characterization of aspects of the phenotype, especially those related to connective tissue defects. Skeletal changes include wormian bones in the lambdoidal and sagittal sutures, anterior rib flaring or cupping, and lateral or medial spur formation on the proximal and distal femoral and humeral metaphyses (53). Decreased bone density and osteoporosis can be seen after an age of 6 months. Arteriography shows tortuosity, narrowing, and dilatation of cerebral, visceral, and limb arteries, relatable to the intimal hyperplasia, and the fragmentation and beading of elastic tissue (54). Radiographic studies also reveal lobular bladder diverticuli in some patients. Gastric polyps have been noted (55), and the clinical course in at least one patient was complicated by a progressive sliding hiatal hernia, a manifestation

**FIGURE 100-2** Facial features in a child with Menkes disease. Note the jowly facial appearance and abnormal hair.

that should be considered in patients with recurrent gastrointestinal or respiratory symptoms (56). MRI of the brain shows intracranial vascular tortuosity, as well as the progressive postnatal decrease in cortical mass, ventricular dilatation, and white matter atrophy.

Patients with milder or atypical manifestations have been reported (57–60). A number of such children were, in fact, severely affected but with a longer life span than “classical” Menkes disease. Such longevity may reflect improvement in supportive care, rather than a distinct clinical variant. However, many such patients have shown a milder phenotype in general, with later onset of symptoms and a less severe clinical course. As such, Menkes disease must be considered a disorder with a spectrum of severity (55), with implications for clinical evaluative considerations in children with psychomotor retardation of unknown etiology.

A specific variant of Menkes disease, at the mildest end of the spectrum of severity, is occipital horn syndrome (OHS), previously called X-linked cutis laxa. While originally proposed as a form of Ehlers–Danlos syndrome (type IX) due to lysyl oxidase deficiency (61), subsequent documentation of abnormal copper metabolism (62) and definitive molecular genetic analyses (59,63–67) confirmed that the OHS is indeed an allelic variant of Menkes disease. The OHS is therefore a connective tissue disorder caused by a secondary deficiency of the cuproenzyme, lysyl oxidase. Hyperelastic and “bruisable” skin, bladder diverticulae, varicosities, hypermobile joints, and skeletal abnormalities including short, broad clavicles, fused carpal bones, thoracic malformations, and bony exostoses of the occiput characterize the syndrome. The OHS is sometimes accompanied by mild neurologic impairment, in contrast to the severe neurologic degeneration of Menkes disease.

**FIGURE 100-3** Phase contrast illumination showing a hair shaft (left) from a Menkes disease patient with 180-degree twisting (*pili torti*) compared with two normal hair shafts (right).

### 100.2.2 Heterozygosity for X-Linked Menkes Disease

While the natural history and variability of clinical expression in affected hemizygotes has been well studied and well documented, little is known about the phenotypic effects in heterozygotes. As with other X-linked recessive disorders, genetic counseling is often experientially based on a presumption of the benignity of heterozygosity. The emphases of the clinical geneticists are therefore placed on the prenatal or postnatal diagnosis and treatment of affected males. While some females with Menkes disease have had X chromosome abnormalities (68,69), others have not (70). It is therefore reasonable to consider that a fraction of heterozygotes may exhibit connective tissue or central nervous system manifestations in varying degrees—based on severity of mutation, skewing of lyonization (71), or other disease mechanisms. As in, for example, ornithine transcarbamylase deficiency heterozygosity, such patients may proceed through diverse medical interventions without a diagnosis or with an incorrect diagnosis. Another study of six female heterozygote relatives of three unrelated hemizygotes with different severe mutations reinforced the admonition mentioned previously (72). Importantly, all heterozygotes showed some measure of mild impairment on cognitive testing or neurologic examination, or both. Integumentary findings were observed on physical examination, and the majority of women showed subtle skeletal abnormalities on bone radiographs. Three women showed blood vessel tortuosity, or premature volume loss, or both, on brain MRI studies. Given the small numbers of well-studied heterozygotes, risk figures for clinically significant manifestations are not calculable. However, it is fair to conclude that there is a finite risk of

clinically significant manifestations in carriers of severe Menkes disease mutations. Further, while some manifestations (e.g. patchy skin findings) may be ascribed to differential lyonization, others (e.g. a spectrum of nonspecific neurologic features) may reflect the more generalized effect of a threshold- and age-based central nervous system copper deficiency (72). Such possibilities should be considered in diagnostic protocols, in genetic counseling, and in making decisions on whether treatment may be indicated for some heterozygotes.

### 100.2.3 Biochemical Pathology

In the patient with Menkes disease, oral copper is poorly absorbed, and there is abnormal distribution of body copper: low levels are found in, for example, plasma, liver, and brain, while excessive accumulation has been documented in other tissues, such as intestinal mucosa, kidney, and placenta. Measurements of cuproenzyme activities in tissues of Menkes disease patients have confirmed reduced specific activities, and it is therefore reasonable to ascribe many of the clinical manifestations to deficiencies of cuproenzymes in multiple tissues. However, studies in cell culture systems have revealed that the pathophysiology is somewhat more complex. Defective copper export is the basic cellular defect observed in cultured cells; with the exception of hepatocytes, all tested Menkes cells exhibit excessive copper accumulation (7). Kinetic studies revealed a specific defect in copper efflux, with normal uptake, and with normal transport of other trace metals in mutant cells under experimental conditions (73–75). These observations led to the hypothesis that defective copper efflux was the consequence of an abnormality in intracellular translocation of copper. This notion was later learned to be consonant with the basic genetic defect and with the cell biology of the Menkes disease transporter ATP7A. Under this construction, copper would be taken up by intestinal mucosal (or renal tubular) cells but not released across the serosal membranes, thereby causing systemic copper insufficiency, reduced cuproenzyme activities, and Menkes disease. Theoretically, treatment might be effected by the bypassing of the intestinal absorptive block. However, additional complexities may be of significance. In particular, a sufficiency of copper availability to a mutant cell can correct some cuproenzyme activities—superoxide dismutase-1 (74), tyrosinase, and cytochrome c oxidase (76)—but not others, such as lysyl oxidase (77). In the case of lysyl oxidase in Menkes mutant cells, holoenzyme formation may be reduced because of inhibition of transcription or reduction in stability of lysyl oxidase mRNA (78). While preliminary and suggestive data are in place for lysyl oxidase, similar considerations may obtain for other, heretofore uncharacterized, copper-dependent functions and may be of importance in the eventual design of effective therapy.

The mechanisms resulting in the developmental cerebral and cerebellar abnormalities are unknown and

under investigation. In an important heuristic approach to this question, expression profiles in Menkes brain tissue were studied using microarray analysis, leading to the observation of significant downregulation of multiple genes, involved in energy metabolism, myelination, and ribosomal function (79). An additional area of investigation is focusing on copper-dependent impairments in energy metabolism, with consequent mitochondrial damage, increased levels of cytochrome C release from mitochondria, and enhanced apoptosis leading to neurodegeneration (80,81).

### 100.2.4 Molecular Pathology

Following the cloning of the gene responsible for Menkes disease, the complete genomic structure was elucidated (82,83), identifying a gene with 23 exons over a genomic region of approximately 150 kb. The Menkes gene, designated as MNK or ATP7A, is expressed in all tissues except liver, a pattern consistent with a housekeeping role in cell copper homeostasis and with the Menkes disease phenotype. Sequence analysis predicts a 1500-amino acid protein, with the structure of a copper-transporting P-type ATPase (37) (Figure 100-4). The N-terminal domains of the protein and of the homologous Wilson disease transporter, ATP7B, have been shown to specifically bind copper (84) and may function as sensors of intracellular copper concentration (85). The MNK protein is localized in the membrane of the trans-Golgi network (39,86–88) and cycles between the trans-Golgi and plasma membrane localizations in response to basal conditions or conditions of copper excess, respectively (38,89). Structural and experimental studies have suggested that the MNK protein contains specific motifs that govern trafficking of the protein to the trans-Golgi network, and retrieval from the plasma membrane (88,89). Based on the aggregate studies, it is apparent that copper dyshomeostasis and disease can result not only from mutations that abolish the transport function of MNK but also from mutations leading to incorrect intracellular localization (40,90,91).

Diverse mutations of the MNK gene have been described in severe Menkes disease, and all such mutations would be predicted to result in severe impairment of the expression, structure, or function of the protein. Approximately, 15% of patients with severe Menkes disease have partial nonoverlapping deletions (92). Additional categories of mutations are different in each family and include nonsense, missense, and splice-site mutations, and small deletions or insertions (93,94). Analyses in patients with milder disease, and especially with the OHS, have revealed splice-site mutations in splice donor or acceptor sites that are not in the invariant dinucleotide sequences at the intron boundaries. In such instances, expression of some fraction of correctly spliced full sequence mRNA would presumably result in the synthesis of a small amount of normal MNK protein

**FIGURE 100-4** Model of ATP7A with functional domains indicated, as well as known amino acid substitutions and their phenotypic correlations. ATP7A has eight transmembrane segments and six copper-binding domains. The protein also has phosphatase, phosphorylation, transduction and ATP-binding domains. The majority of ATP7A missense mutations affect the carboxyl-terminal half of the protein. Early diagnosis and treatment is currently rare in Menkes disease; thus, little is known about the treatment responsiveness of the missense mutations associated with this phenotype. Of the mutations displayed, only two (Gly666Arg and Gly727Arg) have been evaluated in terms of early intervention, and each proved responsive to early treatment. Thus, newborn screening for Menkes disease that would detect affected infants in the first week of life is urgently needed. The locations of missense mutations that cause OHS and isolated distal motor neuropathy are also noted.

and result in the milder occipital horn cell phenotype (59,66,95–97). Cases of the OHS have also been shown to have mutations affecting mRNA splicing, in regulatory regions of the gene (64), and mutations affecting cellular localization (65,98); correlations with the milder occipital horn phenotype are more complex in these cases.

### 100.2.5 Diagnosis and Genetic Counseling

Once the diagnosis is confirmed in a proband by biochemical or molecular studies, genetic counseling proceeds as with other X-linked disorders. In the instance of a singleton case of severe Menkes disease and absent definitive data on maternal heterozygosity, conventional Bayesian calculations may be employed as for other X-linked recessive disorders with male lethality. Diagnosis in the proband may proceed on the basis of clinical, biochemical, and molecular studies, as outlined later in this chapter. Diagnosis in a proband can be confirmed

biochemically, while mutation identification is usually required for definitive documentation of heterozygosity. Rapid and reliable molecular diagnostic protocols have been developed, using sequential stepwise approaches that include multiplex PCR techniques, heteroduplex analyses, RT-PCR, and direct sequencing (99,100). These approaches are being increasingly employed in clinical molecular diagnostic laboratories, enabling physicians caring for Menkes patients and their families to provide accurate diagnosis, heterozygote detection, and prenatal diagnosis.

Serum copper and ceruloplasmin concentrations are decreased when measured beyond the first 6 weeks of life, but these may be indistinguishable from normal when measured in cord blood or during the first weeks of life. The hepatic copper content is markedly decreased, even in the immediate perinatal period (see Table 100-3). Daily urine copper excretion may be increased during the first year of life. Finally, the measurement of plasma and

cerebrospinal fluid catecholamine levels is finding increasing utility in the diagnosis of Menkes disease. In particular, there can be found elevations of dihydroxyphenylalanine (DOPA) and dihydroxyphenylacetic acid (DOPAC), with decreased levels of specific norepinephrine metabolites, or of norepinephrine, or epinephrine themselves (101–104). Elevations in the ratios of DOPA or DOPAC to norepinephrine or derivatives thereof likely reflect dopamine-beta-hydroxylase deficiency, in the face of reduced availability of copper to the central nervous system. Dopamine-beta-hydroxylase deficiency also leads to increased urine ratios (over 4.0) of homovanillic acid/vanillylmandelic acid (HVA/VMA), and this clinical chemistry can also be used to screen patients for Menkes disease (105).

Menkes disease should be considered in any male infant with unexplained seizures, mental retardation, and hypothermia. The hair changes and radiologic findings are especially helpful differential features and might even be used in initial clinical evaluations for possible heterozygosity in female patients with unexplained neurodevelopmental presentations.

Menkes disease and OHS are expressed in cultured skin fibroblasts, and an elevated copper content can be detected by atomic absorption spectrophotometry or as the accumulation of radioactive copper (106). Most characteristically, kinetic studies reveal a markedly reduced efflux of copper in mutant fibroblasts (74). Such studies should be performed by laboratories experienced in these analyses. While the analyses may be employed in the initial assessment of heterozygosity in the presence of a positive family history, there may be as high as a 50% rate of false negativity, and the results must be interpreted with caution.

Second trimester prenatal diagnosis of male fetuses at risk has been performed by copper accumulation and kinetic studies in cultured amniotic fluid cells (106,107). First trimester prenatal diagnosis has been accomplished by measurements of copper content in chorionic villus samples (108). Because of specific sources of ambiguity in both kinds of prenatal measurements, prenatal diagnosis should be performed by a laboratory with extensive experience in tissue copper biochemistry.

Prenatal diagnosis and heterozygote detection have also been accomplished by mutation detection, in instances in which the mutation in a given family was already known or identified as part of the clinical diagnostic sequence (109,110). With respect to the genetic counseling of heterozygotes, it should be noted that there have been instances of recurrence in women who are not carriers of mutations, suggesting that germline mosaicism cannot be excluded as a mechanism in the transmission of the Menkes disease mutations (111). Finally, in practice, clinical molecular diagnosis and the availability of mutation identification may be problematic, since most ATP7A mutations appear to be unique to each family. If, in a given family, the mutation is not already known, the identification of a mutation may take some time, and clinical geneticists should be prepared to avail themselves of accurate biochemical testing protocols for genetic management.

### 100.2.6 Treatment

Postnatal postsymptomatic treatment is predicated on the bypassing of the intestinal absorptive block, by the parenteral administration of copper, usually as copper histidine, as early in the course of the disease as possible. The results of earlier treatment attempts were not encouraging. However, there have been recent reports of therapeutic amelioration of symptoms, in milder or atypical patients, or when treatment has begun very early in life (102,104,112–114). In some instances, significant improvements in neurologic status have occurred, but patients have developed some of the severe connective tissue manifestations of the OHS (112). It has been hypothesized that treatment outcome is primarily predicated on the existence of residual functioning MNK protein (102). A different hypothesis emphasizes that positive effects can be achieved, even in the face of severe mutations, if treatment is to begin very early, perhaps in a baby intentionally delivered prematurely. This latter hypothesis is consonant with the notion that some of the pathology begins in utero (115) and that parenteral copper is more likely to enter the brain prior to the maturation of exclusionary brain transport mechanisms. Given all of these uncertainties—both empiric and theoretical—it must be emphasized that treatment of Menkes disease, at this writing, is investigational; patients should therefore be referred for treatment to centers with ongoing systematic treatment protocols in place.

A combination of gene therapy with adeno-associated virus serotype 5 (AAV5), harboring a truncated (owing to AAV vector packaging limits) but functional version of ATP7A plus copper chloride, both delivered by intracerebroventricular injection, enhanced the survival of *mottled brindled* male mice in comparison with no treatment (116). *Mottled brindled* is a mouse model of Menkes disease based on mutation of *atp7a*, the murine homolog of ATP7A (see mouse models below). AAV5 transduces the choroid plexuses of the cerebral ventricles (117), and these specialized polarized epithelia appear crucial for copper transport to the CNS (118).

Finally, the medical geneticist should ensure that a patient with Menkes disease is treated by an experienced multidisciplinary medical team, including neurologists, nutritionists and gastroenterologists, pulmonologists, urologists, and social service personnel.

### 100.2.7 A Novel ATP7A-Related Phenotype

A third clinical phenotype—distal motor neuropathy without overt copper metabolic abnormalities—was recently found to be associated with mutations in ATP7A in two large families with multiple affected males (119). Distal hereditary motor neuropathies (HMNs) comprise a clinically and genetically heterogeneous group of disorders that predominantly affect motor neurons in the *peripheral nervous system* (PNS) (120). Distal HMNs have been classified into seven main subtypes on the basis of mode of inheritance, age of onset, distribution of muscle weakness, and clinical progression (121). Ten genes associated with distal HMNs have been identified to date (122–124). These genes encode a functionally diverse array of proteins, including two cation transporters (ATP7A and transient receptor potential cation channel subfamily V member 4), a transfer RNA synthetase, two heat shock proteins, and a microtubule motor protein involved in axonal transport.

ATP7A-related distal motor neuropathy is associated with unique missense mutations in ATP7A affecting amino acids within or near transmembrane segments of the protein (Figure 100-4). The resulting amino acid substitutions—Thr994Ile in transmembrane domain 6 and Pro1386Ser in the short extracellular loop between transmembrane domains 7 and 8—may contribute to the abnormal intracellular trafficking phenotype observed with these defects and may prove relevant to the underlying mechanism of this form of motor neuron disease.

### 100.2.8 Clinical Features

As in CMT, type 2 (125), the newly described ATP7A-related phenotype features progressive distal motor neuropathy with less prominent sensory loss (Table 100-4).

Symptoms begin with distal muscle weakness and atrophy of the lower extremities, followed by involvement of the upper limbs, reductions in tactile and vibratory sensation, and loss of deep tendon reflexes. Foot and hand deformities such as pes cavus (Figure 100-2c), hammer toes, and curled fingers are typical (126). The age of onset varies from the first to sixth decade of life, with the majority of cases presenting between 10–35 years of age (122). Nerve conduction studies show reductions in compound motor amplitudes with generally normal ( $\geq 40$ s) conduction velocities (122,126,127), indicative of an axonopathy rather than a demyelinating process. The phenomenon of “dying-back neuropathy,” in which degeneration begins in the distal portions of axons and slowly advances back toward the motor neuron cell body, is usually a result of a metabolic disturbance or toxin. The delayed-onset (often in adulthood) character of ATP7A-related distal motor neuropathy implies that the mutations associated with this disease have subtle effects that require years to provoke pathological consequences.

### 100.2.9 A Novel Mechanism of Disease?

The mechanism underlying ATP7A-related distal motor neuropathy seems to be distinct from the pathophysiology of Menkes disease and OHS. Individuals with ATP7A-related distal motor neuropathy have no neurological problems other than motor neuron disease, and no clinical or biochemical findings similar to those observed in patients with Menkes or OHS (Table 100-5). Specifically, no patients with ATP7A-related distal motor neuropathy, examined to date, have shown hair, skin, or joint abnormalities, low serum copper, abnormal plasma catecholamine levels, or renal tubular dysfunction (122), all of which are considered to be hallmarks of mutations at the ATP7A locus. Conversely, three patients with Menkes disease and four individuals with OHS examined recently showed no clinical or electrophysiological evidence of motor neuron dysfunction (S. G. Kaler, unpublished work). The individuals with OHS included the first patient in whom the condition was molecularly defined (56), who is now 32 years old, and an unrelated individual with OHS, who is now 19 years old (67). At these ages, one would have expected ATP7A-related distal motor neuropathy to be clinically manifest, if a common pathogenetic mechanism were involved. Delineation of the underlying mechanism in this form of motor neuropathy will help elucidate the normal role of ATP7A in peripheral nerve biology. Copper deficiency from various causes is known to induce transient sensory or motor neuropathy (22–28), and both ATP7A and ATP7B are expressed in mouse spinal cord neurons (128); however, the identification of ATP7A-related distal motor neuropathy is the first evidence that ATP7A has a direct role in motor neuron function.

TABLE 100-4 Synopsis of Inherited Copper Transport Diseases							
Condition/ Inheritance Pattern	Age of Onset (yrs)	Neurological Signs	Other Clinical Findings	Clinical Biochemical Findings	Molecular Defects	Treatment Options	Prognosis
Menkes Disease/ X-linked recessive	0–1	Hypotonia; seizures; developmental delay	Coarse hair; jowly facies; lax skin and joints; decreased bone density; bladder diver- ticula; gastric polyps; vascular tortuosity and distension	Low-serum copper and ceruloplas- min; Abnormal plasma and CSF neuro- chemicals; Increased urine $\beta$ 2-microglob- ulin.	Diverse mutations in ATP7A; 0–15% residual function	Early copper replacement	Difficult, u early o treatm (withi of birt
OHS/X-linked recessive	3–10	Dysautonomia; <sup>a</sup> slightly reduced muscle strength	Coarse hair; occipital exostoses; hammer- shaped clavicular heads; lax skin and joints; bladder diverticula; vascular tortuosity and distension	Low-normal serum copper and ceruloplasmin; Abnormal plasma and CSF neurochemicals	Leaky splice junction or hypofunctional ATP7A missense muta- tions; 20–30% residual function	Copper replacement; L-dihydroxy- phenylserine (L-DOPS) for dysautonomia	Fair; long- natural not kn may b for vas proble
ATP7A-related distal motor neuropathy/ X-linked recessive	5–50	Atrophy and weakness of distal muscles; foot drop; decreased or absent deep tendon reflexes; abnormal nerve conduction studies <sup>b</sup>	Pes cavus foot deformity; No other specific clinical abnormalities	No specific lab abnormalities	Missense mutations near luminal loops in carboxyl half of ATP7A (Figure 100-3); 60–70% residual function	None currently recommended (due to incomplete understanding of disease mechanism)	Uncertain natural unkno slow d progre likely
Wilson disease/ Autosomal recessive	3–50	Tremor, spastic rigidity, dystonia, dysgraphia, dysarthria, depression, schizophrenia	K–F corneal rings, jaundice, hepato-megaly, osteoporosis, amenorrhea	Low serum copper and ceruloplasmin; Elevated LFTs; Increased hepatic copper	Diverse mutations in ATP7B; 50% missense. Large deletions rare	Penicillamine Trien Zinc Tetrathio- molybdate	Excellen good c compl
Idiopathic Copper Toxicosis/ Autosomal recessive (presumed)	0–6	Irritability	Jaundice, hepatomegaly, ascites, aminoaciduria	Elevated serum & urine copper; Normal or high serum ceruloplasmin; High hepatic copper	Unknown	Penicillamine	Poor with ages treatm

<sup>a</sup>Syncope, dizziness, orthostatic hypotension, abnormal sinoatrial conduction, nocturnal bradycardia, and bowel or bladder dysfunction.

<sup>b</sup>Decreased peroneal and median muscle amplitudes with normal conduction velocities.

### 100.2.10 Mouse Models of Menkes Disease

The mottled mouse provides an excellent mammalian model for Menkes disease (129,130). The mottled (Atp7a) and human ATP7A loci are located in homologous regions of their respective X chromosomes. The Mouse Genome Informatics database of the Jackson Laboratory lists 88 Atp7a alleles, including 38 spontaneous or induced (through radiation and/or chemical mutagenesis) mutants, as well as 48 gene-trapped and two gene-targeted alleles (131). The molecular bases for 14 Atp7a allelic variants have been characterized (67,131–139). One of the best-studied mouse mutants, the mottled brindled male hemizygote shows tremor, a decrease in coat pigmentation, general inactivity, death at  $\approx 14$  days of age, an increase in intestinal copper levels with low levels of the metal in the liver and in the brain, and reductions in copper enzyme activities (129). Of interest has been the observation that normal viability can be restored in these mutant animals if a single copper injection is provided during the first 7–10 days of life, a response also characteristic of the mottled macular mouse, a biochemically similar model of Menkes disease discovered in Japan (76,139). Nevertheless, at least in *mottled brindled* animals, this treatment response seems to be dependent on modifier genes, as no response to therapy is shown in mottled brindled mice on a homogeneous C57BL/6J background, a strain that often maximizes expression of mutant phenotypes. In contrast to *mottled brindled* animals, mice harboring the *mottled blotchy* mutant allele are viable, even without treatment, although these latter mice show more pronounced connective tissue abnormalities than the former. Cultured fibroblasts from all *atp7a* mutant mice tested have demonstrated increased copper accumulation compared with similar cells from wild-type animals (140).

Investigation of the biochemical phenotype in *mottled brindled* and *mottled blotchy* mutant lines has been extensive (129,131,141–144), while recent cell biological studies have provided new insights into the effects of specific mottled (Atp7a) mutations (145,146). The *mottled brindled* and *mottled blotchy* mutant proteins do not traffic efficiently from the *trans*-Golgi to the plasma membrane in response to elevations in copper (145). The *mottled viable brindled* and *mottled macular* defects each shift the steady-state equilibrium of Atp7a to one where the protein is mainly localized to the plasma membrane under basal copper conditions, whereas mottled 11H, an embryonic lethal allele, encodes an isoform of Atp7a that is unable to exit the endoplasmic reticulum (146). In conjunction with the earlier work (147), the findings in *mottled viable brindled* and *mottled macular* imply that Atp7a trafficking is delicately controlled by phosphorylation and dephosphorylation. Specifically, these mutations seem

to stabilize Atp7a in a distinct conformation that leads to an increase in phosphorylation and alters intracellular localization (146,147).

Embryonic gene replacement accomplished by crossing mottled female heterozygotes with male transgenic strains corrected lethality in *mottled tohm* (a large intragenic deletion of Atp7a) and *mottled brindled* mutant mice (138,148).

The *mottled* mouse mutants will continue to serve as useful agents for the study of Menkes disease and other ATP7A-related diseases, and for evaluation of potential new therapies.

## 100.3 WILSON DISEASE

Wilson disease is an autosomal recessive disorder characterized by increased copper deposition in the liver, brain, and cornea. The clinical features have been described over the past 90 years (149), and the involvement of copper became central to considerations of pathogenesis during the past 50 years (150). In contrast to Menkes disease, Wilson disease is a disorder of copper toxicity (Table 100-5). The basic defect had been broadly understood to reside in impaired intracellular transport of copper into a hepatocyte pool or compartment essential for biliary excretion of copper, and for incorporation of copper into ceruloplasmin. The cloning of the Wilson disease gene, located on chromosome 13q, showed it to be a second P-type ATPase (ATP7B), with 55% amino acid homology to the Menkes disease gene (41–43). As with Menkes disease, the identification of the Wilson disease gene, and the characterization of its function, has greatly advanced our understanding of Wilson disease and its pathogenesis.

### 100.3.1 Clinical Features

Wilson disease has an estimated incidence of 1 per 30,000 (151), can present with quite variable clinical manifestations, and shows a range of age of onset of from 3 to over 50 years of age (151–153). Classically, the disease is characterized by the coexistence of specific neurologic findings that tend to be progressive—chronic liver disease with cirrhosis, renal tubular dysfunction, and pigmented corneal rings. However, the variability of the disease is such that it should be considered in any patient with unexplained neurologic or psychiatric dysfunction, hepatitis, hemolytic anemia, certain skeletal lesions, renal Fanconi syndrome, or hematuria. An earlier age of onset in a given patient is, in general, associated with hepatic disease, often without neurologic manifestations.

Liver involvement in Wilson disease (154,155) may resemble subacute viral hepatitis, chronic active hepatitis, juvenile cirrhosis, posthepatic cirrhosis, and cryptogenic cirrhosis. The disorder can present as chronic or as fulminant liver disease, with liver failure. Early signs of hepatic involvement may be hepatomegaly and jaundice; a patient may also present with the rapid onset of

edema, ascites, or GI hemorrhage. Histologic findings are not specific and range from fatty cellular degeneration to macronodular cirrhosis.

Wilson disease is also a disorder of movement (153,156), and neurologic symptoms generally occur after the second and third decades. Specific manifestations include behavior disturbances, tremors, spasticity, rigidity, dysarthria, clumsiness, abnormalities in handwriting or other fine movements, and deterioration in performance in structured situations, such as school settings. Dystonia may include difficulties with facial muscles and drooling, and patients may appear parkinsonian in presentation.

The symptoms reflect the particular involvement of the basal ganglia in the disorder; pathologically, there is extensive neuronal loss, astrogliosis, and cavitation in the basal ganglia. Psychiatric symptoms—suggesting depression or schizophrenia—may be the signal presentation in as many as 20% of patients (157), and can precede the appearance of movement abnormalities (156). A strictly neurologic presentation is rare in children, and when present, latent liver disease can often be found in such patients.

In psychiatric presentations, changes in personality (irritability, anger, poor self-control), depression, and anxiety are common symptoms. Patients presenting in this fashion are typically in their late teens or early 20s, a period during which substance abuse is also a diagnostic consideration. Wilson's disease should be formally excluded in all teenagers and young adults with new-onset psychiatric signs.

The Kayser–Fleischer corneal ring (Figure 100-5) is the most important ophthalmologic finding in Wilson disease.

**FIGURE 100-5** The occipital “horns” of OHS. Occipital horns (large arrow) are calcified tendons of the trapezius and sternocleidomastoid muscles at their attachment to the occipital bone. The precise basis for these calcifications is not known, but they are not found in patients with classical Menkes disease or ATP7A-related distal motor neuropathy. The formation of occipital horns could represent an inflammatory response to chronic injury of the involved tendons caused by a combination of reduced connective tissue strength from lysyl oxidase deficiency and the capacity of patients with OHS to use these muscles frequently. Wormian bones (black arrow) are extra bone pieces that occur within a suture line in the skull and are not specific for OHS versus Menkes disease.

The ring is a brown-to-green discoloration in the limbic region of the cornea and consists of layers of copper granules in the Descemet membrane. Slit-lamp biomicroscopy is required to conclusively document the presence or absence of the rings. Approximately 95% of patients with neurologic signs manifest the Kayser–Fleischer ring compared with approximately 65% of those with hepatic presentations (158). Copper chelation therapy causes fading and even disappearance of corneal copper over time. While pigmented corneal rings can be seen in other liver disorders, these can be distinguished from Kayser–Fleischer rings by expert examination. Sunflower cataracts (159), which do not obstruct vision, may also be observed (in up to 13% of adult patients) on slit-lamp examination (Figure 100-6).

Age influences the specific presentation in Wilson's disease. Nearly all individuals who present with liver disease are younger than 30 years, whereas those presenting with neurologic or psychiatric signs may range in age from the first to the fifth decade. This reflects the sequence of events in the pathogenesis of this disease (see earlier discussion). However, regardless of clinical presentation, some degree of liver disease is invariably present. In one series of 400 adult patients with Wilson's disease, approximately 50% presented with neurologic and psychiatric symptoms, 20% with neurologic and hepatic symptoms, and 20% with purely hepatic symptoms (160).

Other clinical findings include acute hemolytic anemia with jaundice, which can occur prior to hepatic and neurologic symptoms. Hemolysis results from the direct toxic effects of copper on red blood cell membranes. When it occurs, this is usually associated with release of massive quantities of hepatic copper into the circulation, a phenomenon that can be sudden and catastrophic.

Renal involvement (161) can occur in approximately 50% of patients and includes hematuria and the renal Fanconi syndrome, the latter directly related to the

**FIGURE 100-6** Kayser–Fleischer ring in Wilson disease, representing copper deposition in Descemet's membrane of the cornea. (Image courtesy of T.U. Hoogenraad, MD, University Department of Neurology, University Hospital, Utrecht, The Netherlands.)

toxic effects of copper deposition. The renal tubular dysfunction can have secondary consequences, including phosphaturia and uricosuria. The former can lead to hypophosphatemia, with resultant renal rickets, osteoporosis, bone fractures, and pseudofractures. The uricosuria can result in a low serum urate, a relatively unique clinical chemistry, and a helpful diagnostic clue for Wilson disease. Renal function must be delineated in every patient prior to treatment, because certain therapeutic agents can be nephrotoxic.

Some untreated women may show amenorrhea and impaired fertility. Further, in some adults with longstanding Wilson disease, hepatocellular carcinoma has been observed. Additionally, some patients may have cardiac involvement, including arrhythmias and cardiomyopathy.

### 100.3.2 Molecular Pathology

The Wilson disease gene on the long arm of chromosome 13 (162) was identified by positional cloning strategies, based on the hypothesis that the Wilson disease protein might bear similarities to the Menkes disease transporter (37). The gene, termed WND or ATP7B, is expressed in liver, kidney, and placenta, in contrast to the widespread expression of the Menkes gene. The WND gene encodes a 1411-amino acid P-type copper-transporting ATPase. In the liver, the ATPase is localized to *trans*-Golgi vesicles in the pericanalicular area, with small amounts of the protein in the canalicular membrane (163). In the presence of elevated intracellular copper concentrations, the ATPase is distributed close to the bile canaliculi (164). It is possible that the Wilson disease ATPase interacts with the gene product of the *COMMD1* 1 gene (implicated in a copper toxicosis syndrome in the Bedlington terrier (165)) in the mediation of biliary excretion of copper (166). Such localization, translocations, and possible interactions are consistent with two functions of the WND protein: the transporting of copper into the hepatocyte secretory pathways for incorporation into ceruloplasmin and the excretion of copper into bile (167). Impaired function of the WND protein results in copper accumulation in the hepatocyte cytoplasm and, ultimately, liver cell necrosis, spillover of copper into plasma, and toxicity to extrahepatic organs, including brain (168).

In contrast to Menkes disease, large gene deletions do not occur in Wilson disease patients, and over 50% of the (over 300) WND mutations are missense mutations (169,170). A few mutations in the Wilson disease gene account for a significant fraction of cases in specific populations (41,169,171,172). For example, the H1069Q mutation accounts for 30% of all mutations in European populations, while the R778L missense mutation is common in Asian populations. In addition, Wilson disease mutations are in general associated with specific chromosomal haplotypes in a given population (173). Both

kinds of genetic epidemiologic correlations are applicable to clinical molecular diagnosis.

A Wilson disease mutation database contains over 300 different mutations reported at the ATP7B locus (<http://www.wilsondisease.med.ualberta.ca/database.asp>).

For families in which the mutant alleles have been determined, molecular diagnosis is highly reliable. While there is great variability, and even intrafamilial variability, some broad genotype–phenotype correlations have been described (172,174). For example, mutations such as nonsense mutations, deletions, and duplications, which would be predicted to result in a truncated or absent gene product, tend to be associated with early-onset liver disease. In contrast, the H1069Q missense mutation, in a homozygote or compound heterozygote, generally results in either neurologic or liver disease symptoms in adolescence (151). Even in the case of the H1069Q mutation, studies have revealed no significant differences between H1069Q homozygotes as compared with H1069Q compound heterozygotes in terms of age of onset and clinical and biochemical manifestations (172).

### 100.3.3 Diagnosis and Genetic Counseling

Once a diagnosis has been established in a given patient, genetic counseling can proceed as appropriate for an autosomal recessive disorder. To make the diagnosis of Wilson disease, one can perform a staged evaluation, as outlined later in this chapter. If mutations at both alleles are identified in the proband, then an accurate molecular diagnosis of Wilson disease can be made in presymptomatic or future siblings. The availability of mutation data also enables the accurate assignment of heterozygote status to relatives of a given proband. The problem often faced in clinical practice is the absence of knowledge of the actual mutation(s) in a patient with clinically documented Wilson disease. In such circumstances, and in some families and populations, it may be possible to use haplotype linkage analysis to trace the segregation of mutant genes through a pedigree.

The diverse manifestations of Wilson disease make the diagnosis quite difficult, and, in some systematic surveys, diagnostic errors—and consequent delay in treatment—are frequent (175). In this context, awareness of the multiple presentations of Wilson disease is, indeed, essential so that the diagnosis can be considered in a broad spectrum of patients. Formal recommendations and scoring systems may be helpful as guidelines (169,176). Wilson disease should be included in the differential diagnosis of patients with unexplained hepatic, neurologic, renal, or bone disease, or hemolytic anemia. Kayser–Fleischer rings are an especially important clinical finding on examination, but their absence, especially in the instance of hepatic presentation or in a patient with hemolytic anemia, does not exclude the diagnosis.

Clinical laboratory investigations include measurements of serum copper, urinary copper excretion, serum ceruloplasmin, tissue copper levels, and radiocopper kinetic studies (152–154,177,178). Ceruloplasmin levels (and serum copper concentrations) are decreased in most patients with Wilson disease. However, 4% to 28% of patients show serum ceruloplasmin concentrations in the normal range, and these individuals may show a normal serum copper concentration. Mostly, such patients are children or adolescents with liver disease. Conversely, ceruloplasmin levels may also be low in other conditions, including chronic active hepatitis with or without liver failure. The distinction between Wilson disease and chronic active hepatitis can, in fact, be quite difficult because of the similarity of clinical course, ceruloplasmin levels, and urine copper excretion. Absence of a molecular diagnosis, measurements of hepatic copper concentration, and even radiocopper kinetic studies may be required, to make this distinction.

Urine copper excretion at baseline, and after a dose of D-penicillamine, can be a useful diagnostic parameter. Urine copper excretion in patients is 100 mg/24 h to 1000 mg/24 h, in comparison with the normal excretion of <40 mg/24 h. After a dose of 1 g of D-penicillamine, normal adults will excrete 600–800 mg copper/24 h, while patients with Wilson disease will excrete well over 1000 mg/24 h. Because the excretion of copper reflects excess body stores, presymptomatic patients, or patients diagnosed very early, may have normal excretion values. Conversely, hypercupriuria can be observed with prolonged or severe cholestasis for reasons other than Wilson disease; elevations in urine copper are therefore not specific for Wilson disease.

The copper content of liver, brain, kidney, and cornea is increased in Wilson disease, and hepatic content can serve as a diagnostic discriminator. Hepatic copper content in symptomatic and presymptomatic patients ranges from 2 to 90 times normal, as measured in mg/g of dry weight. For comparison, hepatic copper content in chronic active hepatitis is generally 7–15 times normal.

Patients with intermediate or otherwise indeterminate hepatic copper contents require additional diagnostic testing. For such patients, a specific diagnostic test is the kinetic analysis of plasma and ceruloplasmin radioactive copper concentration after an intravenous dose of  $^{64}\text{Cu}$ . Patients with Wilson disease do not have a normal secondary rise in plasma radioactivity or incorporation of  $^{64}\text{Cu}$  into ceruloplasmin, even in those patients with normal ceruloplasmin levels. (Note that patients with Menkes disease do have a normal secondary response.) In heterozygotes, the rate of incorporation of  $^{64}\text{Cu}$  into ceruloplasmin is decreased compared with normals but is still measurable. This kind of testing should be performed at a center with experience in such analytic protocols.

Finally, mutation analysis may be employed to confirm a diagnosis suspected on the basis of clinical and biochemical parameters. This approach is particularly

important in the absence of typical symptoms, ambiguity of biochemical markers, or in asymptomatic siblings. A stepwise approach to molecular analysis has recently been outlined, beginning with rapid screening for a highly prevalent mutation in a given population or ethnic group (e.g. the H1069Q mutation in European populations). Screening for a panel of additional mutations present in significant frequency can ensue, if necessary, followed by analysis of exons (and intron boundaries). Such systematic molecular testing is becoming increasingly available and has, in fact, been put forth as an additional diagnostic criterion (172,179) for a disorder that requires early and, in some circumstances, rapid intervention.

### 100.3.4 Treatment

The prognosis in Wilson's disease is generally favorable. Current therapeutic approaches can prevent or reverse most of the significant clinical signs and symptoms, including Kayser–Fleischer rings. However, if treatment is stopped, potentially fatal liver damage inevitably occurs. The objective of treatment is to prevent copper from accumulating in tissues. While intake of copper can be decreased by restricting foods high in copper, the mainstay of medical therapy has been the use of the copper-binding agent, D-penicillamine (b,b-dimethylcysteine) (180), in doses of 1 g/d in adults and older children, and 20 mg/kg/d for children under 10 years. Pyridoxine supplementation is required, as D-penicillamine is a pyridoxine antagonist. Therapy is monitored with periodic slit-lamp examinations: there is reduction in pretreatment deposits, but total clearing may require several years (181). Treatment is also monitored by periodic measurements of urine copper excretion: after an initial maximum, excretion should stabilize at 500–800 mg/d during maintenance therapy.

If therapy is begun in presymptomatic patients, the development of symptoms can be prevented. If treatment is begun early in the course of the disease, neurologic and hepatic function can be normalized. However, patients with psychiatric disease may improve, but be left with residual psychiatric symptoms (182). Further, advanced disease may not be reversible, and some patients show neurologic worsening with initial treatment (183–185). D-penicillamine treatment has been shown to exacerbate clinical manifestations in about 50% of patients with neurologic symptoms, and half of those who worsen fail to regain baseline function (21,156). Finally, side effects of D-penicillamine can be serious, ranging from early hypersensitivity reactions (in 25% of patients) to more severe later reactions, including immune complex nephritis, drug-induced lupus erythematosus, Goodpasture syndrome, oral ulcerations, and agranulocytosis. If the drug must be withdrawn in the face of side effects or severe complications, attempts can be made to reinstitute therapy, beginning with very low doses, until the therapeutic range is again achieved.

Since such reinstitution of therapy is not always successful, a number of additional agents have been tested in the treatment of Wilson disease (183). One is the alternative chelating agent, triethylene tetramine HCl (trientine). Trientine is an effective chelating agent, but experience is limited, and the full spectrum of toxicity is not known. A second alternative drug, ammonium tetrathiomolybdate (183,186,187), has been used primarily as a rapidly acting initial treatment for patients with acute neurologic symptoms. In the intestine, this agent complexes copper and food protein, preventing absorption; in the blood, it complexes copper and albumin, making the copper unavailable for cellular uptake (21). In a randomized, controlled, double-blind clinical trial comparing tetrathiomolybdate plus zinc to trientine plus zinc for Wilson disease patients with neurological presentation, a statistically significant decreased occurrence of neurological relapse was found in the tetrathiomolybdate plus zinc treatment group (187).

An increasing number of patients are being treated with oral zinc sulfate or zinc acetate, at 75–100 mg of elemental zinc per day. After a lag of 1–3 weeks, the zinc blocks copper absorption, producing a negative copper balance. The effect is thought to be mediated by induction of intestinal cell MT, which binds copper with high affinity, preventing the transfer to copper into the blood. Treatment with zinc is nontoxic, does not produce initial neurologic worsening, and prevents hepatic reaccumulation of copper. Treatment with oral zinc has been shown to be effective, with clinical amelioration reported in multiple studies (181,184,187–189). Oral zinc may be especially useful for maintenance, following D-penicillamine initiation, or in conjunction with another agent (183,188,189). In pregnant women being treated with D-penicillamine, the teratogenic effects of the drug must be considered. There are reports of connective tissue defects of variable severity following pregnancies, marked by maternal penicillamine use (190). The magnitude of the risk may be low as numerous normal babies have been born to mothers treated with D-penicillamine. Accordingly, a balancing of the risks would suggest that drug treatment should be continued during pregnancy, at 1 g/d or lower doses, with the dose lowered even further near delivery, if a cesarian section is contemplated. Maintenance of oral zinc therapy may prove to be an important nonteratogenic adjunct during pregnancy.

Finally, improvements in the morbidity and mortality of orthotopic liver transplantation have made liver transplant the therapy of significant choice in Wilson disease patients with fulminant hepatitis, or with progressive, unremitting hepatic insufficiency. In general, transplantation results in removal of excess body copper, neurologic improvement, and disappearance of Kayser–Fleischer rings (191–193). Posttransplant patients do not require chelation therapy, and no recurrence of Wilson disease in a transplanted liver

has been reported. This latter observation was, in particular, made in recipients of grafts from living related heterozygotes for Wilson disease (191). Of additional importance is a report of quality of life data in patients who had received orthotopic liver transplants, showing improvement in overall quality of life in this cohort of Wilson disease patients (194).

### 100.3.5 Future Directions

Gene therapy for Wilson's disease is a possibility. Because the Wilson's copper transporter is expressed most prominently and functions most critically in the liver, this organ could be specifically targeted by the use of adenoviral, adeno-associated viral, or replication-deficient lentiviral vectors. Hepatocyte transfer, an alternative to gene therapy, may also be applicable to the treatment of liver-specific metabolic disorders through therapeutic liver repopulation (195). The Long-Evans-Cinnamon (LEC) rat, toxic milk mouse (tx), and Jackson toxic milk mouse (tx<sup>1</sup>) are naturally occurring rodent models of Wilson disease for which specific *Atp7b* defects have been demonstrated (196). A complete gene knock-out (*Atp7b*<sup>-/-</sup>) has also been generated (197). These models should be useful for preclinical explorations of novel therapeutic approaches.

### 100.3.6 Idiopathic Hepatic Copper Toxicosis

A disease variously termed Indian childhood cirrhosis, non-Indian childhood cirrhosis, copper-associated childhood cirrhosis, and, more recently, idiopathic hepatic copper toxicosis may represent a group of similar disorders, or a single entity with a variable spectrum of severity, and a multifactorial environmental and genetic etiology. The disease was first recognized in eastern India in 1887 and, subsequently, was noted in various other regions of that country. Most cases occurred in male infants from middle class Hindu families residing in rural communities. Indian childhood cirrhosis involved massive accumulation of copper in the liver, and development of early cirrhosis and liver failure. Serum ceruloplasmin levels were normal, and the histopathology of Indian childhood cirrhosis, characterized by hepatic necrosis with ballooning, Mallory's hyaline and absence of fatty change, was easily distinguishable from that of Wilson disease. Segregation analyses of multiple families in one study suggested an autosomal recessive inheritance pattern (198).

Heating and storage of foods, including cow or buffalo milk, in copper-containing (brass) vessels and pots in Indian households were implicated as causes of excessive copper ingestion and an environmental etiology for this disorder (199). The hypothesis was supported by a significant decline in the incidence of Indian childhood cirrhosis when this environmental

factor was addressed (200). Further, children who survived treatment with D-penicillamine showed no subsequent evidence of liver disease (115).

However, it since has become apparent that cases of a very similar form of infantile or early childhood cirrhosis may exist in other countries and even in the absence of overt environmental exposure to sources of excess copper (115). In one study of a Northern Germany population isolate, documentation of parental consanguinity implied autosomal recessive inheritance of a predisposition to development of infantile cirrhosis (201).

Studies in fibroblast cell lines from patients with typical Indian childhood cirrhosis excluded abnormal MT induction in response to metals as a molecular mechanism of disease (202). A reverse argument for a genetic factor was derived from studies showing that elevated copper content in a water supply, per se, resulted in no cases of idiopathic copper toxicosis in a region of Massachusetts over a 23-year period (115,203).

In sum, the aggregate data support the notion that the pathogenesis of idiopathic copper toxicosis—a reasonably distinct clinical and histologic entity—does indeed involve the interaction of genetic and environmental factors. In some patients or settings, either of these factors may play the role of a determinant of major effect. Careful study of the pathology, and of copper trafficking and utilization in tissues and cells from cases in population isolates or familial clusters, and from patients who develop disease in the absence of exposure to excess copper, should be of particular value in elucidating the mechanism of this disorder.

### 101.1 INTRODUCTION

Iron is one of the most abundant elements on earth and a vital component of the cellular processes of most living things. It is used in many enzymatic reactions, including multiple steps of the electron transport chain and the tricarboxylic acid cycle, as well as in reactions catalyzed by microsomal cytochromes involved in detoxification of drugs and other foreign substances. The majority of iron functions as oxygen carrier in the heme groups of hemoglobin and myoglobin. In large quantities and when unbound, iron can be highly toxic to cells. Much of iron metabolism involves maintaining a delicate balance between sequestered and free ion, absorption, elimination, and reutilization. Over time, seemingly small changes in this balance can cause disease. Recent advances in understanding the molecular causes of common and rare disorders of iron metabolism have revealed regulatory pathways previously unappreciated, which suggest novel therapeutic strategies.

### 101.2 IRON BALANCE AND THE IRON CYCLE

Under normal circumstances, the total body iron content is maintained within narrow limits. In men, the average

concentration is 50 mg/kg but in women it is only 35 mg/kg, reflecting the high incidence of iron deficiency (1). Most of the body's iron is found in the form of heme, which serves as a prosthetic group on hemoglobin and myoglobin, for the enzymes required for oxidative phosphorylation, for the enzymes involved in splitting hydrogen peroxide, and on other enzymes required for detoxification of chemical agents or drugs. About 30% of iron is stored as a complex formed with ferritin. A small amount is present within the plasma bound to transferrin, the major plasma iron transport protein. There is no significant mechanism for iron excretion other than through cell loss. Daily losses are generally fixed at 1–2 mg/day due to normal epithelial sloughing of the skin and gastrointestinal (GI) tract, menstruation, and stool and urinary losses. With an adequate diet, this amount is absorbed daily through the small intestine. Under the conditions of iron deficiency, the amount of iron absorbed from the diet can be increased to as much as 4–5 mg/day. Thus iron balance is regulated at the level of absorption. In addition to total body iron, the rate of erythropoiesis also influences intestinal iron absorption (2).

Much of the iron contained in red blood cells is recovered and reutilized (3). This cycling process can be viewed as a series of compartments through which iron is passed. Central to the flow of iron within this cycle is the plasma

compartment, where the majority of iron is bound to the carrier protein, transferrin. As much as 90% of the iron bound to transferrin is targeted to developing red cells in the bone marrow, and ~90% of this is eventually incorporated into heme (3). At the end of their 120-day life cycle, red blood cells are phagocytosed by macrophages in the spleen and the iron is recovered. Depending on requirements, a fraction of the recovered iron is stored in macrophages. Under equilibrium conditions or under conditions of increased erythropoiesis, iron is not stored but passed quickly through the macrophages and is released into the plasma compartment. Other tissues also absorb iron for their own use. The liver is the most prominent site, receiving about 5% of plasma iron (3). Iron is also deposited in the liver in pathologic states, especially under the conditions of high transferrin saturation (TS).

### 101.2.1 Dietary Absorption of Iron

Iron is ingested in two principal forms: complexed in heme or as elemental iron. In both cases, the primary site of dietary iron absorption is within the villous tips of

the duodenum. Although heme iron typically constitutes only one-third of dietary iron, it has much greater bioavailability and can account for as much as two-thirds of iron stores. Much of this may be related to heme being more soluble in the alkaline environment of the duodenum. Surprisingly, heme iron absorption does not appear to be as readily responsive to regulation as non-heme iron. Although nonheme iron absorption can be increased by dietary contents such as ascorbic acid, chelators and phytates can bind iron and inhibit absorption (4–6). The inverse relationship between total body iron stores and iron absorption has been known for decades and with recent discoveries of iron transporters and their regulators, a clear picture of these mechanisms has developed. These findings have also led to links between inflammation and iron deficiency. The role of dietary iron absorption is also influenced by the rate of erythropoiesis. Interestingly, iron absorption is increased in anemias characterized by ineffective erythropoiesis where erythroid cells are destroyed within the bone marrow, suggesting that signals from the bone marrow compartment also influence mucosal iron absorption.

## 101.2.2 Molecular Biology of Iron Metabolism

The molecular details of iron storage, transport, regulation, and absorption are described in the following. Table 101-1 lists the known molecules of iron metabolism involved in inherited disorders.

**101.2.2.1 Iron Storage.** Ferritin is a ubiquitous protein found in all cells, where its principal function appears to be storage of iron. Ferritin concentrates cellular iron and protects cells from its toxic effects. Storage iron is sequestered in a hollow sphere composed of 24 ferritin subunits (7). There are two distinct subunits of ferritin: the H subunit of 21,000 MW and the L subunit of 19,000 MW (8). The primary sequences for H and L subunits share 55% identity but adopt similar secondary and tertiary conformations. Multiple isoforms of ferritin have been isolated from different tissues that differ in the number of H and L subunits (9,10). Acidic isoforms contain a greater number of H chains and are characteristically found in cardiac tissue. Basic isoforms are found in the liver, spleen, and plasma. The active gene for the H

subunit is located on chromosome 11, whereas the gene encoding the L subunit is located on chromosome 19 (11,12). Multiple pseudogenes for ferritin subunits that lack regulatory sequences have been described on other chromosomes (13).

**101.2.2.2 Iron Transport.** Iron is transported in the plasma bound to transferrin. Transferrin is a protein of ~75,000 MW, capable of binding two atoms of ferric iron, and is synthesized primarily in the liver (14). In contrast, many cells, especially those that proliferate, rapidly express transferrin receptors on their surfaces. The transferrin receptor 1 (TFR1) exists as a dimer of a transmembrane glycoprotein of 90,000 MW (15,16). Both the transferrin gene (*TF*) and the *TFR1* map to the long arm of chromosome 3 (17,18). Transferrin protein, with two iron molecules (also known as holotransferrin or diferric transferrin), binds with high affinity to transferrin receptors at neutral pH; apotransferrin (lacking iron) does not. The holotransferrin–transferrin receptor complexes are internalized by receptor-mediated endocytosis (19–21). Acidification of the endosome results in the release of iron from holotransferrin, generating

Rare Disorders of Local or Cellular Iron Overload

Atransferrinemia	PKAN, HARP	Aceruloplasminemia	Neuroferritinopathy	Anemia, sideroblastic, spinocerebellar ataxia	Friedreich's Ataxia

apotransferrin (22–24). Apotransferrin is returned to the cell surface, where it dissociates from the transferrin receptor and can be used again as an iron carrier within the plasma.

The biosynthesis of transferrin, transferrin receptor 1, and ferritin is influenced by the amount of iron in the cell. Regulation of transferrin expression occurs at the level of mRNA synthesis, which is inversely correlated with the amount of cellular iron (25). Transferrin receptor 1 synthesis is largely regulated by the stability of its mRNA, whereas ferritin synthesis is regulated at the level of protein translation. Both ferritin and transferrin receptor 1 mRNAs contain stem-loop sequences, known as iron-responsive elements (IREs), which can bind to iron regulatory proteins (IRPs) with high affinity (26).

The binding of IRP to IREs is enhanced by low cellular concentrations of iron. A single IRE is located within the 5′ untranslated region of the ferritin mRNA. In contrast, transferrin receptor 1 mRNA contains multiple IREs within the 3′ untranslated region. This differential placement results in opposite effects on expression: Under the conditions of low cellular iron concentration, IRPs have high affinity for IREs, resulting in binding to the 5′ end of ferritin mRNA and the inhibition of translation. IRP binding to the 3′ IREs increases transferrin receptor mRNA by increasing message stability. The situation is reversed under the conditions of high iron concentration. High iron decreases IRP binding to IREs, allowing efficient translation of ferritin mRNA, but also renders transferrin receptor 1 mRNA less stable and subject to degradation.

Two distinct IRPs have been cloned. The gene encoding *IRP1* maps to chromosome 9, and a second highly homologous gene, *IRP2*, maps to chromosome 15 (27). *IRP1* is a protein of 90,000 MW and has strong homology to mitochondrial aconitase, including all active site residues and three cysteines that serve as ligands for a 4Fe–4S cluster (28,29). Further studies suggest that *IRP1* may function as a cytosolic aconitase (29).

The binding of iron in the 4Fe–4S complex of aconitase is unstable (28,29). This suggests that *IRP1* affinity for IREs is influenced by the stability of the iron–sulfur complex, which can be related to cellular iron concentration (30). If iron is abundant in the cell, the iron–sulfur complex of *IRP1* is stable and the molecule functions as a cytoplasmic aconitase but binds IREs with low affinity; under iron-poor conditions the iron–sulfur complex is destabilized and the molecule loses aconitase activity but binds IREs with high affinity. In fact, the IRE-binding site and the aconitase-active sites overlap, indicating that enzymatic activity and IRE binding are mutually exclusive (31,32).

*IRP2* binds to IREs with affinity similar to *IRP1* (33–35). However, *IRP2* lacks aconitase activity and appears unable to form an iron–sulfur complex (33,36). In addition, unlike *IRP1*, *IRP2* is substantially degraded in the

presence of iron (33,35). Absence of *IRP2* in mice results in misregulation of iron in the intestinal epithelium and neurons of the CNS causing neurodegeneration and iron accumulation in the brain (37). Factors other than iron have been identified that also regulate IRP binding. These include hypoxia, phosphorylation, and certain cytokines.

**101.2.2.3 Iron Absorption.** Nonheme iron is mostly absorbed in the duodenum where ferric iron ( $\text{Fe}^{3+}$ ) in food is reduced to  $\text{Fe}^{2+}$  by the cytochrome reductase *DcytB* and then transported across the apical membrane into the enterocyte by divalent metal transporter 1 (DMT1), also known as divalent cation transporter 1 and natural resistance-associated macrophage protein 2 (Nramp 2), a proton-coupled, divalent metal ion transporter (38). Located on endosomal membranes as well, (39) DMT1 is responsible for the transport of nonheme iron into the intestinal epithelial cell from the intestinal lumen (38). In addition, DMT1 is involved in the transport of iron from the endosome to the cytoplasm. DMT1 is mutated in the microcytic anemia (*mk*) mouse (40), a strain exhibiting a recessive disorder characterized by microcytic hypochromic anemia due to defects in intestinal iron absorption and erythroid iron utilization (41). An orthologous mutation is found in the Belgrade (*b*) rat, which exhibits a similar phenotype (42). Thus DMT1, the iron transporter of intestinal villi, also plays an important role in the transferrin cycle.

Ferroportin (FPN1) functions to export iron out of the intestinal epithelial cells. In yeast, high-affinity iron uptake is mediated by the iron transporter, *FTR1*. The vertebrate equivalent of *FTR1* was identified through positional cloning of the zebrafish mutant, *weissherbst* (43). This mutant develops a hypochromic anemia due to a deficiency in FPN1, which is responsible for the transport of iron from the maternally derived yolk sac stores to the embryonic circulation. Human FPN1 localizes to the basal surface of placental syncytiotrophoblasts, where it transports iron from mother to embryo. It is also highly expressed in the liver and the duodenum, specifically localizing to the basolateral membrane of intestinal epithelial cells and to Kupffer cells of the liver. In addition to placental transport, FPN1 mediates transfer of iron from intestinal epithelial cells into the circulation and the release of iron from macrophages.

Just as the apical flux of iron into the cell is associated with a reductase, the export of iron requires the ferroxidase activity of hephaestin, presumably to promote iron binding to apotransferrin. Hephastin was first identified as the causative gene mutated in the sex-linked anemia (*sla*) mouse, which exhibits a microcytic anemia due to defective intestinal iron absorption. However, unlike the *mk* mouse, the *sla* mouse is capable of normal iron uptake into the intestinal mucosal epithelium but is unable to effectively transfer iron to the circulation (44). Cloning of the gene responsible for *sla* led to the identification of hephaestin, a transmembrane-bound ceruloplasmin homolog, which putatively functions as

a ferroxidase required for the transfer of iron from the enterocyte into the plasma (45).

Although heme iron absorption accounts for a greater percentage of dietary iron absorption, our understanding of its mechanisms remains poor. Two possible mechanisms have been proposed (46). The first theory based on binding and transport studies of heme suggests an active receptor-mediated endocytic pathway. Multiple studies have shown specific binding and energy-dependent uptake of heme by intestinal epithelial cells. Presumably, heme-bound iron is either released by heme oxygenase 2 and transported out of the endosome by DMT1 into the cytoplasmic iron pool following a pathway similar to nonheme iron, or transported intact by the heme-responsive gene-1 (HRG-1) (47). Notably, however, a heme-binding receptor has not been identified to date.

The second possible pathway for heme iron absorption involves three recently identified heme transporters: heme carrier protein 1 (HCP1), also known as proton-coupled folate transporter (PCFT) and SLC46A1, feline leukemia virus subgroup C cellular receptor 1 (FLVCR), and HRG-1 (SLC48A1). HCP1/PCFT was originally isolated by a subtractive hybridization technique in hypotransferrinemic mice and was shown to be expressed on the apical membrane of duodenal epithelial cells and mediate heme transport (48). Interestingly, HCP1/PCFT has independently been shown to function as a proton/folate symporter and several mutations in HCP1/PCFT have been associated with hereditary folate malabsorption (OMIM 229050) (49–53). Sequence analysis of *HCP1/PCFT* in a multiethnic cohort found mutations to be rare and not associated with iron overload (54).

Within the intestinal epithelial cell, iron may be released from heme by endoplasmic reticulum bound heme oxygenase 1 and follow the nonheme iron-bound pathway. Alternatively, FLVCR and/or HRG-1 may be involved in its transport across the basolateral membrane where it is bound to hemopexin (55). FLVCR serves as a heme exporter in erythrocytes and has a critical role in maintaining heme homeostasis within these cells (56). In addition, FLVCR is expressed in the intestinal cell line called Caco-2. However, further studies are needed to elucidate its role in intestinal iron absorption. HRG-1 was initially identified in a gene array study of heme responsive genes of *Caenorhabditis elegans*, which are heme autotrophs and thus completely dependent on heme transport (47). Functional studies have demonstrated that HRG-1 does transport heme and is localized not only to endosomes but also to the basolateral membrane of polarized epithelial cells (57).

### 101.2.3 Regulation of Intestinal Iron Absorption and Body Iron Trafficking

The primary method of regulating iron stores is by modifying dietary absorption through the mucosal villi of the duodenum. Normal iron homeostasis depends on

dietary iron absorption to match the 1–2 mg of normal daily losses, with the capacity for increasing iron absorption under conditions of iron deficiency to 5 mg/day. In concert with the regulation of intestinal iron absorption, body iron stores are also regulated so that iron stores are released in states of iron deficiency. While evidence supporting the role of local iron concentration in the regulation of iron homeostasis has been reported, a more complex regulation involving multiple input signals has become clearer over the past decade.

Under certain conditions such as acute iron deficiency, intestinal iron absorption can be induced by direct intestinal factors including the upregulation of intestinal *DMT1* and *Dcytb* through hypoxia-inducible factor (*HIF*) 2 $\alpha$ -mediated signaling (58). In addition, some *DMT1* transcripts contain an IRE in the 3'-UTR and are stabilized by IRP binding while an IRP in the 5'-UTR of *FPN1* inhibits translation.

More relevant to the long-term maintenance of iron stores is hepcidin, the key regulator of iron homeostasis. Hepcidin is a circulating hormone similar to defensins. It is synthesized by hepatocytes, circulates in the blood, and inhibits the export of iron from intestinal epithelial cells by FPN. Hepcidin binds directly to FPN inducing its internalization and degradation in a Jak2-dependent manner (59,60). Presumably, hepcidin, via its effect on *FPN1* in reticuloendothelial cells, would similarly inhibit iron egress from these cells as well. In nearly all genetic conditions of iron overload, there is a deficiency of hepcidin or defect preventing its interaction with FPN. In contrast, inflammatory states are characterized by excessive hepcidin levels driven by IL-6 and resulting in hypoferremia.

Expression of hepcidin can be regulated by several signal pathways, but the precise nature by which iron is sensed remains unclear. A link with the bone-morphogenic protein signaling pathway was an unexpected observation of mice genetically engineered to lack *Smad4* in hepatocytes which were found to develop severe hepatic iron overload (61). The mutant animals also had 100-fold lower levels of hepatic hepcidin mRNA. In addition, the stimulation of the upstream signaling pathway of SMAD with several of the bone morphogenic proteins (BMPs) induced hepcidin in control hepatocytes suggesting that SMAD4 positively regulates hepcidin expression. Subsequently, BMP6 has been found to be the key ligand in this pathway (62,63).

The full activation of BMP requires a BMP receptor (BMPR) as well as hemojuvelin (HJV), a glycosylphosphatidylinositol-linked membrane-bound protein that can be regulated by matriptase-2 (also known as transmembrane protease, serine 6 (TMPRSS6)), a cell surface serine protease. (64) When activated, matriptase-2 cleaves HJV preventing it from functioning as a BMPR coreceptor (65). HJV can also be secreted in a soluble form, which acts in an opposite manner to inhibit hepcidin expression by binding BMP (66).

The regulation of hepcidin by iron is not well understood, but appears to be regulated through the interaction between TFR1 or transferrin receptor 2 (TFR2) with the hemochromatosis gene product, HFE (67). Unlike TFR1 which is ubiquitously expressed, TFR2 expression is restricted to the liver (68). Both receptors bind to HFE but at different domains (69,70). HFE can compete with transferrin for TFR1 binding, which is believed to sequester HFE from the cell surface and prevent its association with TFR2 (71). In contrast, the binding of TFR2 by HFE and holotransferrin results in the induction of hepcidin expression possibly through ERK1/2 signaling.

This chapter describes clinical disorders that arise from derangements in molecules that are part of the iron metabolic/regulatory pathway. In most cases, the clinical consequences of these disorders result from iron deficiency, iron overload, or anemia. Particular attention is given to classic hereditary hemochromatosis (HH), which is the most common and best studied of genetic disorders of iron metabolism. While many questions concerning iron regulation remain unanswered, many subtypes of iron overload syndrome, types 1, 2a, 2b, 3, and 4, and several molecular mediators have been identified (Table 101-1). Further details, where known, concerning structure–function relationships of these molecules, are discussed below in reference to individual genotypes and phenotypes.

### 101.3 SYNDROMES OF IRON OVERLOAD

Several clinical syndromes characterized by increased body iron stores have been identified (Table 101-2). Typically, these are classified as primary or secondary disorders of iron overload. Various classification schemes have been proposed for the primary disorder, but no consensus has been reached. Nevertheless, five disorders leading to iron overload can be classified as primary disorders and are characterized by clinical, biochemical, and genetic criteria. Whether they should all be classified as “hemochromatosis” is a matter of semantics. The most extensively studied of these disorders is the classic HH (MIM #235200), which affects adults in their later life and is caused by mutations in the *HFE* gene. Juvenile hemochromatosis (JH or HFE2, MIM #602390) is a syndrome similar to HH, but presents with massive iron loading in the second or third decade. Cardiac involvement is usually a prominent feature. Two genes have been implicated in this form of iron overload. Rare cases have been reported with mutations in the *HAMP* gene, which encodes hepcidin. However, most cases show a pattern of recessive inheritance that maps to chromosome 1q (72–74). Mutations in the hemojuvelin (*HJV*) gene suggest that this is the causative gene (75,76). A variety of mutations in the *TfR2* gene have been characterized as a rare cause of iron overload in families without typical mutations in *HFE* and has been classified as HFE3 (77–80). Mutations in *SLC11A3* (FPN1) produce iron overload in an

#### Other Neurological Disorders Associated with Abnormal Iron Handling

PKAN (MIM #234200)  
 HARP syndrome (MIM #607236)  
 INAD (NBIA2A, MIM #256600)  
 Atypical neuroaxonal dystrophy (NBIA2B, MIM #610217)

autosomal dominant pattern and have been classified as HFE4 (81–85).

The genetic basis of other primary disorders of iron overload including neonatal hemochromatosis (NH), African iron overload, and a disorder in a population in the Solomon Islands, has not been identified. NH (MIM #231100) is characterized by prenatal onset of liver disease and extrahepatic iron deposition that spans the reticuloendothelial system. NH is not genetically linked to chromosome 6p or mutations of the *HFE* gene. Recently, it has been proposed that NH is the result of a maternal alloimmune reaction and that iron loading is only secondary to the hepatitis (86). African iron overload (MIM #601195) was first described in the Bantu tribe of Africa, and was thought to be due to excessive dietary iron found in ale brewed in cast-iron drums. Recent studies, however, suggest a strong genetic influence on the development of this condition (see below). Dominant inheritance of an iron-loading syndrome has been identified in a population on the Solomon Islands. Eason et al. described a 96-member Melanesian kindred with 31 cases of iron overload (87). Liver biopsies from

19 of these patients showed features similar to those of the HFE-linked autosomal recessive HH in Caucasians. However, this family showed a pattern of autosomal dominant inheritance, with the involvement of three and possibly four consecutive generations, with a high frequency of transmission from parents to children and equal gender distribution. Linkage and segregation analysis support autosomal dominant inheritance, with no demonstrable HLA linkage.

Iron overload may also occur as a result of multiple transfusions such as those in sickle cell disease or from disrupted iron metabolism due to an underlying disease. Clinically, the iron overload in these conditions may be indistinguishable from primary disorders of iron overload. Generally, iron loading may occur as a result of ineffective erythropoiesis or chronic liver disease. The former includes sideroblastic anemia and thalassemia while the latter is frequently seen in alcoholic liver disease, chronic hepatitis C and B, and nonalcoholic steatohepatitis (NASH).

### 101.3.1 Hereditary Hemochromatosis

The French internist Armand Trousseau is credited with the first case report of hemochromatosis in 1865 (88). The term “Hemochromatosis” was later coined by the German pathologist Von Recklinghausen (1899) as a clinical condition characterized by the classic triad of hepatomegaly, diabetes, and bronzing of the skin (89). The disease was thought to be caused by a “chromogenic” substance carried in the heme, hence its name. Sheldon later suggested that the disease was an inherited process and established the link with abnormal iron metabolism (90). Simon et al. established the recessive nature of inheritance and linked the syndrome to the major histocompatibility complex (MHC) on chromosome 6 (91). In 1996, Feder et al. identified the *HFE* gene and delineated the mutations therein responsible for the clinical condition. These mutations may lead to excessive iron loading, evidenced by biochemical markers of iron stores and subsequently, organ damage and the clinical manifestations of HH. Although many still consider HH a rare disease, population-based testing has demonstrated a prevalence of C282Y homozygotes of five per 1000 among the white populations in the United States, Europe, and Australia, making it the most common inherited disease of the liver (92,93).

The cause of iron overload in HH is misregulation of dietary iron absorption in the duodenum, the site of highest iron absorption in humans. Normally, homeostasis of body iron levels is maintained by regulating intestinal iron absorption. When iron stores are adequate, liver hepcidin expression is induced. Hepcidin circulates to the duodenum where it binds FPN, which is then degraded preventing the export of iron into circulation. In the periphery, downregulation of FPN increases stored iron in macrophages by inhibiting the release of iron. In HH, there is a failure to downregulate intestinal

iron absorption despite adequate body iron stores. This causes an insidious accumulation of iron in the body with no compensatory mechanism of elimination. In addition, the failure to inhibit iron release from macrophages leads to increased levels of circulating iron and preferential accumulation in parenchymal cells. Over time, excess iron accumulates in vulnerable tissues, such as the liver, causing cirrhosis and possibly hepatocellular carcinoma; in the heart, causing congestive failure and dysrhythmias; in the pancreas, causing diabetes; in the skin, causing melanoderma; and in organs of the endocrine system, causing amenorrhea or loss of libido. Although it appears the symptoms of HH are due to iron-related injury, iron depletion does not reverse all of the clinical features, particularly arthropathy. It has been suggested that the degree of symptoms depend on the degree of overload, age, and sex, along with other genetic modifiers and comorbidities. Generally, older patients present with vague complaints of malaise, abdominal pain, or arthritis. Younger patients generally present with amenorrhea or cardiac symptoms.

The diagnosis of HH is made by a combination of clinical suspicion and biochemical and genetic testing. At the least, elevated iron stores in the body without a clear cause for secondary iron overload should lead the clinician toward a diagnosis. TS is almost universally increased in patients with hemochromatosis with a rise in serum ferritin levels later, indicating the accumulation of iron in tissues. Although serum ferritin measurements are a good reflection of body iron stores, they can often be elevated secondarily to chronic inflammation, alcohol abuse, steatohepatitis, and obesity, which may confound the diagnosis of HH. While fasting, TS values exceed 50% and 60% for women and men, respectively, the sensitivity is 0.92 with a specificity of 0.93. At this cutoff value, the positive predictive value is ~86%. Lowering the cutoff of transferrin to 45% predictably increases sensitivity, but will likely include HH heterozygotes and diseases of relatively minor iron overload. Instead, the pairing of serum ferritin with TS has a sensitivity of up to 94%, better than either test alone (94,95). Liver biopsy is no longer necessary for diagnosis in most cases and is often considered optional, with a shifting focus toward prognostication and evaluation of concomitant diseases. Prussian blue stain classically shows the accumulation of iron in parenchymal cells and the advanced disease will likely show nodular cirrhosis.

Phlebotomy remains the treatment of choice but must be started before irreversible tissue damage has occurred. In early studies, 27% of untreated patients developed advanced cirrhosis and hepatocellular carcinoma. Later studies show that phlebotomy leads to some improvement in the severity of hepatic fibrosis, the management of varices, and some reversal of hypogonadism (in young men) and cardiac dysfunction (92,96–98). Phlebotomy is inexpensive and is widely available. Early recognition of signs and symptoms, and aggressive screening in families

of newly described probands are the cornerstones of successful management.

**101.3.1.1 Clinical Features.** Intracellular iron overload carries a toxic burden that affects the heart, pancreas, endocrine system, joints, and most consistently, the liver (95). Iron-related oxyradicals promote the peroxidation of lipid membranes and subsequently, organelle disruption and cellular toxicity. If left unchecked, this process can contribute to hepatocellular necrosis, stellate cell activation, fibrosis, and eventual cirrhosis. Excessive iron accumulation occurs when the total body burden of iron reaches ~8g. In males, this typically occurs in the fourth decade of life. In females, menstruation delays iron accumulation for about a decade and symptoms usually begin after menopause. This may explain why, in adults, HH is found 2–10 times more frequently in males than in females (99–101).

The earliest studies of HH were criticized for lacking control groups and the notable exception of patients with milder disease. The signs and clinical symptoms at the time of diagnosis of HH have changed over time as awareness and screening have increased. Older studies of HH cohorts involved the most severely affected while screening studies of large populations suggest that most individuals with HH have no significant disease. In a cohort of German patients, cirrhosis was present in nearly 80% of those diagnosed between 1947 and 1969, compared to only 44% in those diagnosed after 1970 (102). Similarly, an Italian study of a prospectively collected cohort of patients with hemochromatosis, diagnosed between 1976 and 2007, indicated that patients diagnosed in recent years are more likely to have disease characterized by milder iron overload and lower prevalences of cirrhosis and extrahepatic manifestations of iron loading (103). Of note however, was that the risk of developing hepatocellular carcinoma in cirrhotic patients did not change over the years.

Common symptoms of HH include weakness, abdominal pain, arthralgia, loss of libido, and amenorrhea (102). Some degree of weight loss, fatigue, and lethargy are almost invariable complaints at the time of presentation, with extreme fatigue in 46% (104–106). Abnormalities in liver-associated enzymes are found in over 70% of patients at the time of diagnosis. Common physical findings include hepatomegaly, increased skin pigmentation, loss of body hair, and splenomegaly (102). Arthralgias and fatigue are the most common early symptoms, occurring in over 20% of precirrhotic HH individuals (101,107,108).

Just as the liver has tremendous capacity for regeneration, it also has an impressive ability to store iron. This capacity to accumulate iron within hepatocytes is the main reason it requires years before the development of symptoms. Hepatomegaly is a frequently observed sign of liver disease and is associated with the presence of cirrhosis, although it may often be lacking in the young asymptomatic homozygous patient (95,109). Up

to 93% of symptomatic adult patients have a palpable liver (100,110). Serum bilirubin and transaminases may be normal or slightly elevated, but usually not greater than twice normal (111).

As with many other causes of cirrhosis, HH is often associated with diabetes mellitus but apparently at a higher frequency. In addition, the glucose intolerance described in HH patients is often more severe than in other forms of cirrhosis (111,112). The abnormal glucose tolerance of HH is due to both impaired insulin secretion by pancreatic islet cells and peripheral insulin resistance (113,114). Recent research has found reduced insulin sensitivity in non-HH subjects with greater iron stores, raising the possibility that even moderate degrees of iron excess may result in increasing degrees of glucose intolerance, as with type 2 diabetes (97,115). Diabetes had been previously seen in up to 83% of adult patients with HH, including nearly 20% of HH patients without cirrhosis (90,101,102,104).

The characteristic skin hyperpigmentation (melanoderma) is seen only in very severe forms of HH. When pronounced, it is often gray but sometimes brownish bronze, diffuse in distribution, and mainly affects the sun-exposed areas of the skin. The pigmentation is not iron but rather melanin induced by iron's effects on melanocytes in the setting of epidermal thinning (116,117). Hemosiderin is also present in varying quantities in the dermal basement membranes of eccrine sweat glands or in the connective tissue stroma surrounding these cells. Mucosal pigmentation may also be seen, with slate-gray patches in the mouth. About half of the patients show cutaneous atrophy, ichthyosiform changes, and flattening of the nails or true spoon nail (118). Loss of body hair is also a common skin finding in these patients without clear improvement after treatment.

Arthritis is an early and common symptom of HH in approximately one-third to one-half of the patients (100,111,119–122). Joint involvement can often be severe, especially in patients with substantially elevated ferritin and the damage can require replacement of joints (122,123). The first, second, and third metacarpophalangeal and proximal interphalangeal joints are typically involved, with the next likely being the wrist and knee joints. Radiographic studies frequently show subchondral cyst formation, and bone demineralization is a common finding (124). Degenerative joint disease, osteophyte formation, and joint-space narrowing are present in 64% of patients (121). Unfortunately, phlebotomy does not prevent the onset or progression of arthritis and may even worsen these symptoms (111,119).

Heart disease is present in 15–20% of adult patients, usually as congestive heart failure and arrhythmias, such as atrial fibrillation (125). Electrocardiographic abnormalities consist of a decrease in QRS amplitude and T-wave flattening or inversion. Echocardiography typically shows ventricular dilatation and global dysfunction (126), but restrictive features have also been described

(127). The cardiac implications of HH are still evolving, but recent evidence suggests a correlation with essential hypertension (96,98). The extent to which iron loading causes cardiac symptoms is also unclear, as it is possible that oxidative stress in asymptomatic patients may be related to left ventricular diastolic dysfunction (128).

**101.3.1.2 Pathophysiology of HH.** A similar model to physiological iron regulation can be found in normal glucose regulation; whereas the secretion of insulin by the pancreas regulates glucose levels, and the production of the protein hepcidin by the liver regulates the absorption and mobilization of iron (129). As detailed earlier in this chapter, hepcidin, a protein encoded by *HAMP*, binds to the cellular iron exporter, FPN1 and induces its degradation. Through a signaling pathway that involves HFE as well as TFR2, HJV, and BMPR, excessive iron leads to an upregulation of hepcidin expression (129,130). Inflammatory agents such as interleukin 6 also upregulate hepcidin production. In cases of low iron, the synthesis of hepcidin is downregulated, leading to increased intestinal absorption and mobilization of iron. The core problem in HH is a genetic defect in HFE that impairs the signaling pathway leading to decreased synthesis of hepcidin. This, in turn, results in a failure to adequately reduce intestinal iron absorption and an inappropriate two- to fourfold increase in dietary iron absorption (131–133). In both HH and normal individuals, the percentage of iron absorption is inversely related to body iron stores (131–136). However, when body iron stores are replete or elevated, HH patients fail to downregulate both heme and nonheme iron absorption. This problem is compounded because iron excretion is a nonregulated process; that is, there is no physiological mechanism for excreting excess iron. Over the progression of years, this results in the insidious accumulation of toxic levels of iron in vulnerable tissues. The precise mechanism through which reactive iron induces cellular oxidant damage involves lipid peroxidation, DNA modifications, and protein damage (137). While the majority of iron is bound to ferritin or transferrin and is not available for redox reactions, a component of the nontransferrin-bound iron, the labile plasma iron pool, is available to catalyze the formation of reactive oxygen species as a Fenton agent, catalyzing Haber–Weiss reactions and it is this fraction that is notably elevated in HH (138). Iron and hydrogen peroxide ( $H_2O_2$ ) produce reactive oxygen species that cause tissue damage via oxidation of lipids, polyunsaturated fatty acids, and proteins along with nucleic acids (139).

As discussed previously, the progressive accumulation of iron in the liver may lead to fibrosis and eventually cirrhosis. The initial deposition of iron is primarily in the pericanalicular hepatocytes, with greatest concentration in the periportal hepatocytes. When an unclear threshold of iron accumulation is reached, cirrhosis ultimately develops. Although there is perhaps a role for inflammatory mediators, HH is relatively unique

among progressive liver diseases for a lack of inflammation prior to the development of serious disease. It is primarily thought that sideronecrosis activates macrophages, which along with activated Kupffer cells, release profibrotic cytokines (140,141). Stellate cells are also a critical part of the progression toward cirrhosis in HH, although their exact role is yet to be determined.

The frequency of *p53* mutations in the liver tissue of HH subjects is suggestive of oxyradical damage, although the exact mechanism by which *p53* mutations occur in hemochromatosis is not known. The direct mutagenic properties of iron also likely contribute to the development of hepatocellular carcinoma in these patients. Although hepatocellular carcinoma is a known complication of all causes of cirrhosis, other liver diseases rarely have such high rates of *p53* mutations (142). Evaluating the DNA from 170 cases of hepatocellular carcinoma, Vautier et al. found that 29% of all cases incurred *p53* mutations (143). *p53* mutational clustering was seen in 10 of 14 (71%) hepatocellular carcinomas from HH patients with A:T to G:C transitions at codon 220 in five cases. This mutation would be predicted to change a tyrosine residue to cysteine within the core domain of *p53*, the region that interacts directly with DNA. However, A:T to G:C transversions are not consistent with iron-induced oxidation of guanine to 8-hydroxy-2-deoxyguanosine, a frequent measure of oxidant DNA damage. In a separate study by Hussain et al., higher frequencies of G:C to T:A transitions were seen at codon 249 and C:G to T:A at codon 250 (144). This was also seen with the in vitro treatment of normal human fibroblasts with  $H_2O_2$  and  $FeCl_3$ , resulting in G:C to T:A transversions at codon 249 of the *p53* protein (145). Carmichael and colleagues did not find an increase in 8-hydroxy-2-deoxyguanosine in liver DNA from HH patients, but they did observe enhanced levels of bulky DNA lesions (146). Subsequently, they found a fourfold higher level of etheno-DNA adducts in HH livers compared to controls (147). These findings suggest that lipid peroxidation and subsequent modification of DNA bases may be an important mechanism in the formation of hepatocellular carcinoma in HH. Of interest, the aforementioned Hussain study also demonstrated that 28% of HH cases demonstrated higher levels of inducible nitric oxide synthase in the liver. Although more commonly associated with Wilson's disease (60% of cases), this could potentially implicate nitric oxide as a source of increased oxidative stress (144).

**101.3.1.3 HFE Gene.** Up to 90% of HH patients of northern European ancestry are homozygous for the same 845 G-to-A mutation of the *HFE* gene, resulting in a substitution of the cysteine to tyrosine at codon 282 (C282Y mutation) (148). HFE is highly expressed in hepatocytes and its importance in iron regulation has been confirmed by hepatocyte-specific knockouts of the *HFE* gene in mice. Feder et al. first identified the *HFE* gene by a positional cloning approach genotyping a cohort of

101 HH patients with 45 CA-dinucleotide markers saturating the distal MHC region on chromosome 6 (149). A number of genes were found in close proximity to markers D6S2240 and D6S2233, which described a peak of genetic association spanning 600,000 base pairs. One candidate gene, eventually named *HFE*, encoded a novel MHC class I-like protein whose relationship with iron metabolism was initially unclear. Later, a second mutation was identified in individuals heterozygous for the C282Y mutation but still with clinical evidence of HH. These patients carried a C-to-G transversion at position 347 in exon 2, resulting in a change from histidine to aspartic acid at residue 63 (H63D). Sequence analysis of the translated product initially suggested that the C282Y mutant protein fails to associate with  $\beta_2$ -microglobulin ( $\beta_2m$ ), which is required for surface expression of MHC class I protein. Consistent with these findings was the prior description of the  $\beta_2$ -m deficient mouse recapitulating HH (150–152). Subsequent biochemical analysis of the HFE protein confirmed that the C282Y mutation significantly reduces cell surface expression of the HFE- $\beta_2$ -m complex in transfected cells, while the H63D mutation has little to no effect on  $\beta_2$ -m binding (150,151). Thus, the C282Y mutation has a much more pronounced effect on HFE protein function than H63D.

Genetic knockout studies have since shown that mice lacking HFE develop iron overload and other features similar to HH, including a high TS and accumulation of iron in hepatocytes (152). Of note, these mice develop more severe iron overload than “knock-in” mice homozygous for the orthologous C282Y mutation of HFE (153).

**101.3.1.4 HFE Protein.** The HFE protein is expressed in all tissues except for the brain (154), with a prominence in duodenal crypt cells. A possible mechanism for the involvement of HFE in iron metabolism was first suggested by studies showing that HFE associates physically with the TfR (151,155,156). Biochemical studies show that HFE can form a ternary complex with TfR and transferrin (157). The interaction between wild-type HFE and TFR is pH dependent, with high-affinity binding observed at the basic pH of the cell surface and no binding at the acidic pH of the intracellular vesicles. Transfection studies of HFE in a variety of cell types have led to conflicting conclusions regarding the consequences of this binding. Transfection of the human duodenal adenocarcinoma cell line HuTu-80 with wild-type HFE leads to decreased ferritin and increased TFR. This is consistent with inhibition of transferrin-bound iron uptake by intestinal epithelial cells (158). This contradicts the *in vivo* studies of *Hfe*-deficient mice, however, which demonstrate the impaired uptake of plasma transferrin by the duodenum, suggesting that HFE promotes uptake of transferrin-bound iron by intestinal epithelial cells (159). Nonetheless, most studies in which HFE is overexpressed have reported reduced uptake of transferrin-bound iron (155,160).

Following the identification of TfR2 and hepcidin, it became clear that the primary role of HFE is to regulate

hepcidin expression through its interaction with TfR2 on hepatocytes. HFE has been shown to bind to both TfR1 and TfR2, competing with transferrin in the former and noncompetitively in the latter (161). In contrast to the binding to TfR1, which involves the  $\alpha$ -1 and  $\alpha$ -2 domains of HFE (69), binding with TfR2 occurs via the  $\alpha$ -3 domain of HFE (70). In addition, the binding sites for holotransferrin and HFE overlap on TFR1 but not on TFR2 (69,162). Ultimately, the interaction between HFE and TfR1 and TfR2 results in changes in hepcidin expression. For example, mice with a mutation that prevented the interaction of Hfe and TfR1 displayed high levels of hepcidin (71). In contrast, mice carrying mutations favoring constitutive binding of Hfe to TfR1 exhibited low levels of hepcidin suggesting that TfR1 serves to sequester HFE, preventing its interaction with TfR2, thereby decreasing signaling for hepcidin expression. Accordingly, holotransferrin competes with HFE for TfR1 binding and allows HFE to interact with TFR2.

The C282Y mutation disrupts a disulfide bond of the alpha-3 domain that is critical for correct folding and association with  $\beta_2m$ . MHC class I proteins require  $\beta_2m$  for normal trafficking from the Golgi to the cell surface. The outcome of transfection studies with *HFE* mutants and transferrin receptor would therefore be predicted by the amino acid sequence. The H63D substitution is in a loop within the  $\alpha$ -1 domain, where the histidine participates in a salt bridge. The H63D mutation disrupts this salt bridge and may thereby cause a local change in the tertiary structure of the protein that could affect the function of the HFE protein. The C282Y mutant is not expressed on the cell surface, and therefore does not bind transferrin receptor and does not inhibit cellular iron accumulation. In contrast, the H63D mutant is expressed on the cell surface of transfected cells, but has little effect on cellular iron accumulation. Neither of these mutations has been found to alter the affinity of HFE for TfR1.

The importance of hepcidin in the development of HH has been well established. Decreased levels of hepcidin are associated with higher levels of serum and tissue iron, and liver hepcidin mRNA is inappropriately low in patients with *HFE*-associated HH (163,164). Moreover, forced expression of hepcidin prevents iron loading in *Hfe*-deficient mice (165). In the C282Y mutation, the HFE protein fails to interact with TfR1 and/or TfR2, causing a decrease in the necessary inhibitory pathway.

**101.3.1.5 Genetics.** Sheldon first proposed that hemochromatosis was caused by a generalized disturbance of cellular iron metabolism that prevented iron from exiting the cell (90). Simon and colleagues (91) demonstrated that the inheritance of the hemochromatosis gene is associated with inheritance of certain HLA alleles, and Kravitz and coworkers (166) established formal genetic linkage with certain HLA alleles, thereby fixing the gene location nearby the MHC region on chromosome 6p21.3.

Based on the population distribution of HH, Simon and colleagues postulated that the HH allele originated in a Celtic population (167). Analysis of the C282Y mutation has lent further support to this hypothesis. The Celts first appeared in Europe, north of the Alps around 1000 BC. Although never a united empire, the Celtic culture spread throughout central, southwestern, and south-central Europe. Present-day “Celts” include the Irish, Scots, Welsh, and Bretons. These populations have an increased C282Y allele frequency of 0.069 compared to Anglo-Saxon (0.059), southern European (0.025), and Russian (0.018) populations (168,169). The C282Y allele frequency of 0.065 in Nordic populations of Denmark, Sweden, Finland, and Norway is similar to that found in Celtic populations. Two hypotheses might explain the high frequency of C282Y in the Nordic population. The first contradicts Simon’s original hypothesis that the allele originated in a Celtic population. It states that the C282Y mutation originated in a Nordic population from which the Celts were derived. Alternatively, the C282Y mutation may have been brought to Nordic populations during invasions of Celtic populations, around 900 AD. Based on the linkage disequilibrium surrounding the C282Y mutation and recombination frequencies in this region, Ajioka and colleagues (170) estimated that the C282Y mutation originated 60–70 generations ago. Assuming an average generation time of 20 years, the C282Y mutation is estimated to have occurred around 600–800 AD. This is most consistent with the latter hypothesis and a Celtic origin of HH. However, other estimates place the origin of the C282Y mutation as early as 4000 BC (171–173).

Several authors have commented on the possible selective advantages the HH phenotype might offer. Cazzola and coworkers (174) proposed that the HH allele has been maintained in the population as a result of a heterozygote advantage. The proposed advantage is the slightly increased iron absorption in the heterozygote, but to a degree that is unlikely to produce iron overload. In times of war and famine, when iron in the diet is scarce, the heterozygote may have an advantage. Ritter and colleagues (175) speculated that the HH phenotype could be beneficial in conditions of iron deficiency: homozygous males would not lose reproductive capacity from testicular effects; and females, homozygotes, and perhaps heterozygotes as well, would be better prepared to meet the increased iron demands of pregnancy. In this regard, the phenotype could favor multiparity in that it might help to avoid iron deficiency in the pregnant mother. In fact, females heterozygous for the C282Y mutation have a lower incidence of iron deficiency than controls (176). Rotter and Diamond (177) offer an evolutionary biologist’s perspective of HH stating “That the hemochromatosis gene is considered deleterious at all reflects a male-chauvinist evolutionary view: increased iron absorption is good for most women. From an unbiased

evolutionary view, the deaths of some post-reproductive males are a small price to pay for protecting many women in the same population against anemia.”

More recently, resistance to intracellular pathogens has been proposed as a potential advantage of the C282Y mutation (178). Iron deficiency has long been and continues to be the most common single nutrient deficiency worldwide and the *HFE* gene is conserved throughout vertebrates. Therefore, a unique selective pressure may have been operative during the expansion of the C282Y mutation. In Europe, this may have included epidemics of *Yersinia pestis* (Black Plague) and *Mycobacterium tuberculosis*. Both of these pathogens are intracellular organisms that can evade immune defenses of macrophages and are more virulent in the presence of iron. Although this may seem antithetical, if iron overload did not occur until later in life, if ever, the relative iron-deficient state of macrophages may have added additional protection for these infections.

**101.3.1.6 Penetrance and Modifiers.** HH is a disease of variable penetrance. Biochemical penetrance defined as elevated iron indices is incomplete, with 75% of men and 50% of women homozygous for C282Y showing evidence of iron loading. Although previous estimates ranged as high as 50%, newer data suggest the frequency of clinical sequelae of iron overload is particularly low in women and ~25% in men (179). Complicating the study of the natural history of HH is the latent period, in which iron is deposited in tissues over years of clinically silent disease. The factors that contribute to the varying expression of disease manifestations may include factors that potentiate iron loading or modify the disease phenotype (e.g., accelerating the progression to cirrhosis) and may include both genetic factors that influence iron metabolism, inflammation, or fibrosis. Additional non-genetic risk factors include age, diet, insulin resistance, and alcohol intake (Table 101-3) (148,180).

Evidence of strong concordance between iron overload and disease severity among related individuals has been identified in several studies, but is consistent with shared genetic or environmental factors (181–185). However, a study of monozygotic and dizygotic twin pairs showed that the pattern of residual variation in serum iron indices, after adjusting for the effect of the C282Y mutation, was consistent with additive effects of multiple genes (186). After correcting for age and body mass index, the proportion of variance explained by additive genetic factors was estimated to be 23% and 31% for iron, 66% and 49% for transferrin, 33% and 47% for TS, and 47% and 47% for ferritin for men and women, respectively. In addition to these studies in C282Y homozygotes, a genome-wide association study of healthy adolescent twins and siblings on serum markers of iron status identified not only the *HFE* C282Y association, but also associations between a *TM6RS6* SNP and serum iron and multiple *TF* SNPs and serum transferrin (187). Specifically, the variants in transferrin

**TABLE 101-3 Potential Modifiers of Hereditary Hemochromatosis Expression**

Modifier	Effect on Iron Loading	Effect on Liver Cirrhosis	Reference
<i>Environmental Factors</i>			
Gastric acid suppression	Reduced venesection requirements in those using proton pump inhibitors	<i>Unknown</i>	(219)
Dietary tannins	No significant effect on venesection requirements	<i>Unknown</i>	(217)
Dietary iron intake	Positive correlation between dietary heme iron intake and serum ferritin in postmenopausal women	<i>Unknown</i>	(134)
Blood donation	No significant difference in venesection requirements	<i>Unknown</i>	(487)
Alcohol consumption	Decreases hepcidin and increases iron loading in mouse model of HH	9-fold greater incidence of cirrhosis in those drinking more than 60g/day	(214)
Viral hepatitis	<i>Unknown</i>	Infection with hepatitis C virus was associated with cirrhosis at a younger age and with lower hepatic iron concentration	(215)
Hepatic steatosis	<i>Unknown</i>	Steatosis on biopsy correlates with fibrosis prior to venesection	(220)
<i>Genetic Factors</i>			
Hepcidin ( <i>HAMP</i> )	Rare alleles p.[Arg56X], p.[Arg59Gly], and c.[−153 C>T] have been associated with severe iron loading in <i>HFE</i> C282Y homozygotes		(196,197)
Hemojuvelin ( <i>HJV</i> )	Rare alleles p.[Lys101Pro] and p.[Gly320Val] have been associated with severe iron loading in <i>HFE</i> C282Y homozygotes		(488)
Haptoglobin ( <i>HP</i> )	Conflicting results on effect of Hp2-2 polymorphism on serum ferritin levels and venesection requirements		(198–201)
Tumor necrosis factor ( <i>TNF</i> )	Conflicting results on effect of c.[−238G>A] and c.[−308G>A] on various measures of iron loading	Conflicting results on effect of c.[−238G>A] and c.[−308G>A] on cirrhosis	(202,203,489)
Transforming growth factor-β ( <i>TGFB1</i> )		Single study associated p.[Arg25Pro] with cirrhosis	(204)
Myeloperoxidase ( <i>MPO</i> )	c.[−463G>A] was not associated with elevated serum ferritin and hepatic iron index	c.[−463G>A] was associated with cirrhosis in the same study	(205)
Mitochondrial DNA (mtDNA)	mtDNA [16189 T>C] was associated with biochemical iron overload in <i>HFE</i> C282Y homozygotes		(206)
Bone morphogenic protein 2 ( <i>BMP2</i> )	dbSNP rs235756 was associated with higher serum ferritin and venesection requirements but has not been replicated		(207–209)
Cytochrome b reductase ( <i>CYBRD1</i> )	dbSNP rs884409 was with lower serum ferritin		(209)
Matriptase-2 ( <i>TMPRSS6</i> )	dbSNP rs4820268 was associated with lower TS adjusting for <i>HFE</i> genotype		(187,209)

(*TF*) along with the C282Y mutation at *HFE* accounted for ~40% of variations of serum transferrin levels.

The earliest studies searching for genetic modifiers reported more severe phenotypes in individuals carrying the ancestral HLA-A3/B7 haplotype (188,189) or the HLA-A1/B8 haplotype (190,191) suggesting genetic modifiers within the MHC region. However, these associations have not been consistently observed in more recent studies (190,192–194).

Rare alleles found in genes associated with other forms of iron overload syndromes have been identified in some severe cases of HH. There have been severely affected C282Y patients found to have rare *HAMP* and *HJV* mutations, accounting for a very small proportion of disease variants (195). Island et al. also showed massive iron overload in a C282Y homozygote with a C to T transition in the *HAMP* promoter sequence (196). This particular mutation was found within a BMP-responsive element,

decreasing the transcriptional activity of the *HAMP* promoter and the ability to bind to the SMAD protein complex (196). Further, variants in the *HAMP* gene have been associated with severe disease phenotype (197).

More common alleles in candidate genes have also been associated with both iron loading and liver disease severity. However, in most cases, including *HP*, *TNF*, *TGFB1*, and *MPO*, replication has been inconsistent or limited to a single study (198–206). The most recent example was a study of 592 C282Y homozygotes from France in which multiple SNPs spanning genes linked to non-*HFE* hemochromatosis (*TFR2*, *HAMP*, and *SLC40A1*) and to hepcidin expression (*BMP2*, *BMP4*, *HJV*, *SMAD1*, *SMAD4*, *SMAD5*, and *IL-6*) were genotyped and a significant association was detected between serum ferritin level and a common SNP in *BMP2* (rs235756) ( $P=4.42 \times 10^{-5}$ ) (207). However, a subsequent study by the same investigators failed to replicate the association with serum ferritin, though they did find an association with the amount of iron removed by phlebotomy (208). Indeed, another study also failed to replicate the association between this *BMP2* SNP and serum ferritin (209). This same study involving 863 subjects stratified by *HFE* genotype found that an SNP in the promoter of *CYBRD1* (rs884409) was associated with significantly lower serum ferritin levels in C282Y homozygotes and accounted for 11% of the variance in serum ferritin levels in C282Y homozygotes (209). Interestingly, in heterologous expression assays this polymorphism resulted in a 30% decrease in basal promoter activity consistent with its protective effects against iron loading.

Regardless of whether or not insulin resistance begets iron overload, or the reverse, the resultant oxidative stress likely contributes to the progression of steatosis. Recently, Hatunic et al. studied insulin secretion and insulin sensitivity in patients with HH, showing that a significant proportion (28%) of recently diagnosed HH subjects had abnormal glucose tolerance with insulin resistance (97). Furthermore, this study suggested that HH is an independent risk factor for abnormal glucose tolerance and possibly implementing glucose tolerance testing of individuals with hemochromatosis. Of interest, phlebotomy has been suggested to improve insulin sensitivity in patients with NASH, along with a decrease in alanine transaminase (210). The concept of glucose intolerance as an intrinsic risk factor of HH is still being studied. The normalization of ferritin and transferrin by phlebotomy in HH has also been shown to improve glucose tolerance in some patients (those with impaired glucose tolerance) but has little effect on insulin secretion (97). Regardless, interventions to normalize iron levels in subjects with HH and abnormal glucose metabolism should be started early to prevent progression to diabetes and the development of diabetes-related comorbidities.

In addition to the genetic factors associated with disease expression, several nongenetic factors clearly play a role. Age has a significant effect on the disease burden, as

iron accumulates over time. Cirrhosis and other complications of HH do not generally occur until serum ferritin levels rise above 1000 µg/L (211,212), which typically occurs in men at 50 years of age, or older (179,213). Female sex is generally thought to be protective due to iron losses from menstruation and pregnancy. Alcohol intake and chronic viral hepatitis C are risk factors for cirrhosis by themselves and may accelerate liver fibrosis progression directly or through enhanced iron accumulation (214,215). Hepcidin concentrations had previously been shown to be significantly lower in alcoholic liver disease subjects compared to healthy controls. In mice, hepcidin is downregulated by alcohol and accompanied with an increase of DMT1 and FPN1 (216).

The effects of dietary factors such as dietary iron, vitamin C that promotes iron absorption, and tea which contains tannins that inhibit iron absorption, have been suggested to modify the expression of iron loading in C282Y homozygotes but the evidence is limited (134,217). Interestingly, low serum copper levels have been associated with higher serum and hepatic iron levels, perhaps acting through ferroxidase activity of hephaestin and ceruloplasmin (218). Use of proton pump inhibitors that can cause iron deficiency due to altered gut acidity may also suppress the absorption of dietary iron in HH (219).

Obesity and nonalcoholic steatohepatitis are also important modifiers of HH. This is particularly important in the United States, where there has been a dramatic increase in obesity rates. The CDC estimates that by 2009, only Colorado and the District of Columbia had a prevalence of obesity less than 20%. Of this number, at least 20% of the obese population has significant steatosis. NASH is defined by histopathological changes on liver biopsy (macrovesicular steatosis, mixed inflammatory infiltrate, hyaline bodies, etc.) that are similar to those of alcoholic liver disease, in the absence of significant alcohol use. Insulin resistance is an important step in the progression of liver disease in patients with underlying diabetes and obesity. An association between liver steatosis and fibrosis in HH has been reported in one study (220).

**101.3.1.7 Prevalence of HH.** The prevalence of HH based on genetic and biochemical criteria has been well established in several large studies of various populations throughout the world. Before the identification of *HFE* as the hemochromatosis gene, biochemical studies estimating the prevalence of HH—defined by elevated TS and/or ferritin—ranged from 0.002 to 0.005 in the white populations of Australia, France, Scotland, Sweden, and the United States (221–226). In 1988, Edwards and colleagues (227) published the results of a screening study involving 11,065 presumably healthy blood donors in the state of Utah (227). Subjects with a TS of more than 62% underwent HLA typing, serum ferritin measurements, and liver biopsy. The HLA-identical siblings of probands also underwent liver biopsy. A TS of more

than 62% in an HLA-identical sibling was accepted as evidence of an HLA-linked abnormality of iron metabolism. This study demonstrated homozygosity for HH in men at a frequency of 0.0045. These studies clearly show that HH is the most common genetic disease affecting the liver, and is one of the most common recessive metabolic disorders in white populations (228). It is most common among individuals of northern European descent, and particularly those of Nordic or Celtic origin (229).

Cross-sectional studies of the frequency and distribution of the two *HFE* mutations in different populations confirm this association (168,230). The frequency of the C282Y mutation is highest in individuals of northwestern European origin, particularly in Ireland and the west coast of Brittany where allele frequencies of 0.094–0.142 have been reported (231–233). Allele frequencies ranging from 0.075 to 0.085 have been reported from parts of the United Kingdom, including Aberdeen, East Anglia, and Jersey as well as Oslo, Norway, and Umea, Sweden (234–237). A gradient of decreasing frequency of the C282Y mutation occurs from northwest to southeast with C282Y allele frequencies less than 0.01 in parts of Italy, Portugal, Spain, and Greece (238–243). Outside of white populations, the C282Y allele is rarely found in the indigenous populations of Africa, Central and South America, Eastern Asia, and the Pacific Islands. Interestingly, the H63D mutation has a global distribution that is somewhat similar to that of C282Y, and is most frequent in Europe, Asia Minor, and the Indian subcontinent and rare in Africa and among indigenous populations in Central and South America. The H63D mutation is more common than the C282Y mutation, found in 15–40% of European populations.

The prevalence of clinical HH varies depending on the criteria used for diagnosis and the geographic region studied. However, in general, studies of patients with HH agree with the findings on the geographic variation

in *HFE* mutations. Homozygosity for C282Y is present in 60–100% (average 85%) of white patients with clinically diagnosed HH (Table 101-4) (108,149,244–251). Highest rates of C282Y homozygosity are reported among patients who are of northern European extraction. Lower rates are found in patients from southern Europe (230,249,252), and few instances of homozygosity for C282Y have been reported among African-Americans with iron overload (253–255).

Although the C282Y mutation has a relatively high frequency in many populations and homozygosity is found in the majority of clinical hemochromatosis, questions remain regarding the disease burden of HH. Estimates of clinical penetrance as discussed above, suggest 25–50% of C282Y homozygotes develop iron overload and 10–25% develop some form of HH-related morbidity (256). Several large screening studies have previously been undertaken to assess the prevalence of biochemical iron overload and disease due to iron overload in HH. Olynyk and colleagues (213) screened 3011 unrelated adults of Bussleton, Australia, and identified 16 (0.5%) individuals who were homozygous for C282Y. Twelve underwent liver biopsy, which revealed fibrosis in three individuals and cirrhosis in one who also had a history of alcohol abuse. Symptoms that the authors attributed to HH were present in eight of the 16 C282Y homozygotes. However, a similarly sized study from a primary care clinic in Rochester, New York, identified 12 individuals as homozygous for C282Y, with none having evidence of cirrhosis or cardiac failure (257).

One of the largest of these studies involved the screening of 41,038 individuals at a health appraisal clinic in San Diego, California (258). All patients answered a health survey and were examined by a physician; 152 C282Y homozygotes were identified and compared to controls from the same population. Although C282Y homozygotes were more likely to report “liver problems” and to

**TABLE 101-4 Genotype Frequencies for *HFE* Mutations in Patients with Hemochromatosis**

have an elevated serum aspartate amino transferase level, there was no greater prevalence of diabetes, arthralgias, or heart disease. Liver biopsies were not performed, so little can be concluded about the degree of liver injury. Similarly, a Norwegian study of 65,238 individuals using biochemical markers, followed by genetic testing, identified 269 individuals with HH, but only four, all men, had advanced liver disease (99). In African- and Asian-American populations, HH and the C282Y mutation are uncommon (230,254,255,259–262). In Beutler and colleague's study of 9650 individuals, allele frequencies of C282Y by ethnicity were reported to be 0.063 for Whites, 0.027 for Hispanics, 0.002 for Asians, and 0.051 for Blacks (263). In their larger study of the same population, the prevalence of C282Y homozygotes was 0.0046 in Whites but only 0.0025 in Hispanics and 0.0023 in those reporting a mixed race or race other than those listed (258). No C282Y homozygotes were identified in over 1400 African Americans. The low frequency of iron overload and the C282Y allele in African-Americans is supported by the Rochester study where 16,031 primary care patients were screened, including more than 2000 African-Americans; only 25 patients—all White—were confirmed to have HH by liver biopsy (255). Of an additional 20 patients with TS consistently greater than 45%, serum ferritin greater than 200 mg/L, and no obvious cause of secondary iron overload, only one was African-American. Thus, the prevalence of clinically diagnosed HH based on the 45 patients was 0.0056 among Whites and 0.0009 among African-Americans.

In the Hemochromatosis and Iron Overload Screening (HEIRS) study, almost 100,000 participants from ethnically diverse populations were recruited and tested for TS, serum ferritin, and C282Y and H63D mutations of *HFE* (130). The estimated prevalence of C282Y homozygotes was higher in non-Hispanic whites (0.0044) than in Native Americans (0.0011), Hispanics (0.00027), Blacks (0.00014), Pacific Islanders (0.00012), or Asians (0.00000039). However, despite the lowest prevalence of C282Y, Pacific Islanders and Asians had the highest geometric mean levels of serum ferritin and mean TS, and of the 364 participants in whom iron overload had not been diagnosed and who had a serum ferritin level greater than 1000 µg/L, only 29 were C282Y homozygotes. These findings illustrate that iron overload syndromes in non-White populations may be even more common than *HFE*-related hemochromatosis. At this time, the genetic and pathophysiological basis of these common conditions is largely unknown.

#### 101.3.1.8 Diagnosis and Differential Diagnosis.

Diagnosis of HH occurs in three general settings: (1) when an isolated proband presents with suggestive clinical features, laboratory evidence of excessive iron stores, and a liver biopsy showing the characteristic features of iron deposition with fibrosis or cirrhosis; (2) in the investigation of relatives of a diagnosed proband; (3) in the setting of population screening or serendipitous

screening, as may occur with routine blood work as part of a regular health maintenance program. Because each setting reflects different relative risks of having HH, the diagnostic workup differs. Even within a given setting, additional factors such as age, sex, and history of chronic blood loss must be considered.

Physicians and healthcare workers must be aware of the early minimal signs, such as a slightly enlarged liver or metacarpophalangeal arthropathy, and of their value for early diagnosis. Appropriate laboratory tests and possibly liver biopsy should follow. Prenatal diagnosis is not recommended since penetrance is highly variable, symptoms due to fully penetrant HH are preventable, and a full and productive life can be expected with pre-symptomatic diagnosis and treatment. General population screening is currently not recommended (256).

Biochemical testing for iron overload is useful for both screening and management of HH. The most useful biochemical tests are TS (serum iron/total iron-binding capacity  $\times$  100) and serum ferritin. In adult HH patients, serum iron levels are commonly greater than 170 mg/dL (30 mmol/L). However, because serum iron alone correlates poorly with body iron stores, it is not a satisfactory test for screening.

TS is an early and sensitive indicator of iron overload. In a study of 537 subjects from 18 pedigrees, a TS above 62% correctly identified 92% of homozygous siblings of known HH patients (223). In the same study, the serum ferritin concentration identified only 72%. The TS is the most reliable single laboratory test for screening in children and adults (222,264–269). As a screening tool, TS has been established as the preferred biochemical test. The sensitivity and specificity depends on the cutoff value used. TS  $>45\%$  has a sensitivity of 98% and identifies 6.3% of the population, whereas a cutoff of  $>60\%$  has a sensitivity of 86%, with 1.1% of the population called positive (270–272). Sensitivity is also affected by sex, with the same cutoff being more sensitive in males than in females. For universal screening purposes, the increased sensitivity of a lower cutoff must be weighed against an increase in false positives. Assuming a prevalence of 0.45% in the population, a cutoff of 45% would have a positive predictive value of 7%. Alternatively, a cutoff of 60% would have a positive predictive value of 35%.

Serum ferritin is a practical test for estimating total body iron stores and the severity of iron overload in otherwise healthy individuals. Ferritin is an acute-phase reactant and is elevated in states of inflammation. C-reactive protein and erythrocyte sedimentation rate can help distinguish between an elevated ferritin due to increased iron stores and that due to inflammation. Normal values for serum ferritin range between 20 and 350 mg/L and are age and sex dependent. In normal subjects, 1 mg/L of ferritin correlates with 140 mg of iron storage per kilogram of body weight (273).

A combination of serum ferritin and TS seems to be more sensitive than the individual measurement of each,

with a sensitivity of 94%, specificity of 86%, positive predictive value of 73%, and a negative predictive value of 97% (265,266,274–276). Serum ferritin has previously been demonstrated to correlate well with mobilized body iron in healthy control subjects and in patients with advanced HH (224,277,278). Bassett (266) showed an excellent correlation of serum ferritin with body iron stores, even in young homozygous subjects with early iron overload. In contrast, serum iron concentration has a low sensitivity and specificity and poor predictive value for detecting homozygotes. Unbound iron concentration (UBIC) has been proposed as a more cost-effective screening tool. Unlike the two-step TS, UBIC is a single-step test. The validity of UBIC has been confirmed in large screening studies, but has not gained widespread acceptance (279–281).

The high frequency of the C282Y mutation in HH has made the testing of this mutation invaluable for the diagnosis of HH. In the setting of increased TS, homozygosity for C282Y confirms the diagnosis of HH without the need for further testing. Confusion often arises in the interpretation of C282Y/H63D compound heterozygotes and H63D homozygotes. Both of these genotypes are common in the normal population and carry only a small relative risk of developing clinical manifestations of HH (282). Depending on the clinical situation, liver biopsy may be indicated to establish the diagnosis in these situations. Other sequence variants have been identified but their contribution to HH has not been established. S65C is a single base-pair substitution of A by T at nucleotide 193, which leads to a serine to cysteine missense. This is in the region implicated in transferrin receptor binding (283). After correcting for the presence of C282Y, Arya and associates found no difference in the frequency of S65C in voluntary blood donors with TSs greater than 45%, compared to those less than 45% (0.017 vs. 0.022, respectively) (284). Parametric analysis by others, however, shows a significant increase in mean TS when S65C is present compared to the wild-type allele (285). In addition, the frequency of S65C is increased on non-C282Y/non-H63D chromosomes in HH compared to controls (0.16 vs. 0.02, respectively) (286). A novel mutation was identified in an individual heterozygous for C282Y and with typical features of HH. A G to T substitution at position +1 of intron 3 was identified and shown to result in loss of exon 3 in the mature transcript (287).

Prior to the identification of the *HFE* gene, liver biopsy and hepatic iron index (HII) were generally required for the diagnosis of HH (288,289). Early in the course, liver biopsy shows stainable iron in the periportal areas. In the later stages, it is widely distributed throughout the hepatic lobules. The extent of stainable parenchymal iron in the liver is graded from 0 to 4, with grades 0 to 1 being normal. Grades 2–4 indicate increased parenchymal iron stores. Grade 4 stainable iron is usually seen with advanced disease. In HH, unlike in secondary iron

overload syndromes, hepatocytes rather than Kupffer cells are preferentially loaded with iron.

The hepatic iron concentration is the most objective means of assessing body iron stores (288). The range of normal values is 5–40 mmol/g (mean 15 mmol/g). In advanced disease, the hepatic iron concentration frequently exceeds 150 mmol/g. Because iron normally accumulates in tissues with age, the HII (hepatic iron index = hepatic iron concentration/age) corrects for this normal process (290). Originally developed to discriminate heterozygous from homozygous HH, a HII >1.9 was later shown to differentiate HH from alcoholic liver disease (288,289,291). However, a HII >1.9 has been reported in many different forms of cirrhosis. In fact, of 106 liver transplant patients nearly one-third had evidence of HH by serum iron indices. Four of these patients had a HII >1.9, but none were homozygous for C282Y (292).

Nevertheless, liver biopsy may still be a valuable tool in certain individuals. The identification of established fibrosis portends an increased risk of hepatocellular carcinoma even after iron depletion. Factors that have been associated with liver fibrosis include age greater than 40 years and serum ferritin greater than 1000 mg/L. If any of these conditions is present, liver biopsy should be strongly considered (212,293).

Noninvasive methods for measuring tissue iron content, by computed tomography (CT) (109,275,294) or superconducting quantum interference device (SQUID) biomagnetic liver susceptometry, have been reported to be helpful in the diagnosis of hepatic iron overload (295,296), but their low diagnostic accuracy has limited their use in the past. Magnetic resonance imaging (MRI) has more recently been accepted as a noninvasive method for quantification of hepatic iron (297,298).

CT evaluation of the liver in HH demonstrates increased attenuation and correlates with serum biochemical studies, but not with HII (299–301). In addition, imaging studies cannot differentiate between parenchymal cell iron deposition consistent with HH and Kupffer cell iron deposition seen in other iron overload syndromes. Initial studies on the use of MRI did not prove to be reliable in assessing iron stores (302,303). Recent modifications have been used to establish a method of MRI imaging that correlates hepatic iron concentration and the natural logarithm of the ratio of the signal intensity of liver to the standard deviation of background noise ( $r = -0.94$ ). SQUID biomagnetic liver susceptometry measures also correlate with liver iron stores, but its availability is limited (304–306). Recently, its use in the imaging of fetal liver iron overload has been suggested, possibly prompting ante- or neonatal treatment in severe cases (307).

Historically, the distinction between advanced HH and secondary causes of iron overload, particularly alcoholic cirrhosis, has been difficult, as the pathologic findings are often similar (288). HH patients who use alcohol

to excess have compounded the confusion in analyzing clinical studies. The use of the HII had resolved much of the confusion by delineating the lesser hepatic iron content typical of alcoholic liver disease, when corrected for age. LeSage and coworkers (308) demonstrated that the hepatic iron content in alcoholic HH patients was the same or even less than for age-matched nonalcoholic HH patients, but well within the hepatic iron levels diagnostic for HH. The iron overload observed in patients with alcoholic liver disease has been suggested to be caused by the heterozygous state for the HH gene. However, they are clearly unrelated with no significant increase in C282Y prevalence among patients with alcoholic liver disease (309).

In addition to chronic liver diseases, iron overload consistent with HH has been reported in patients with beta-thalassemia trait (310), hereditary spherocytosis (311–313), refractory sideroblastic anemia (314,315), and congenital dyserythropoietic anemias (316). The presumed etiology for iron overload in these patients is increased iron absorption caused by ineffective erythropoiesis. A study of 40 patients with acquired sideroblastic anemia demonstrated that significant iron loading occurred in the absence of either the C282Y or H63D mutation (317). On the other hand, a significantly higher frequency of coinheritance of the C282Y allele was found in 18 unrelated X-linked sideroblastic anemia hemizygotes (318).

Porphyria cutanea tarda (PCT) has also been associated with increased iron due to alcohol, (see Chapter 99) chronic hepatitis C, and HH (319–322). Clinical improvement with phlebotomy supports the role of iron in the pathogenesis of PCT. Alcohol is an important factor in certain regions and is involved much more often than any other, including the *HFE* gene. In other regions where alcohol intake is lower, the expression of PCT could depend on other factors, including the *HFE* gene. Mutational analysis of *HFE* in several populations, including North America, Australia, Britain, and Italy, have clearly demonstrated that both the C282Y and the H63D mutations are cofactors in the expression of PCT (323–326).

Patients on hemodialysis also frequently have elevated iron indices, but C282Y does not appear to increase the risk of iron overload in these patients (327). Individuals who receive more than 60–100 blood transfusions for chronic anemia (aplastic anemia, chronic renal failure, and refractory anemias) are at high risk of developing parenchymal iron deposition and associated organ toxicity (328,329). Early clinical signs of iron overload, including hepatomegaly, carbohydrate intolerance, and cardiac arrhythmias, are noted with the accumulation of 10g of iron. Congestive heart failure is noted with 75–100g of iron (329,330). Reports of prolonged oral iron therapy causing iron overload syndrome are infrequent, although there is a tendency among some physicians to treat microcytic anemias empirically with iron (331).

**101.3.1.9 Population Screening.** Population screening for HH and *HFE* mutations specifically is not recommended (256,332,333). Not all C282Y homozygotes will develop clinical features of hemochromatosis, and some homozygotes will never present with iron levels high enough to warrant phlebotomy. Several investigators suggested implementing screening for HH in different populations even prior to the identification of the *HFE* gene (227,265,276,334,335) and the American College of Pathologists and other experts advocated screening by serum iron indices (332,336,337), but because of concerns over cost effectiveness and genotype–phenotype correlation, others argued against screening (338–340). The World Health Organization (WHO) and the US Preventive Services Task Force have developed general criteria for population screening of genetic diseases (341,342), and HH meets many of these. The WHO criteria as specifically applied to HH:

1. First and perhaps the most compelling criterion promulgated by the WHO for population screening is that the condition should be an important health problem. Although HH is the most common inborn error of metabolism in people of European descent, the age distribution of C282Y homozygotes was no different than controls in Beutler and colleagues' study suggesting that there were no significant differences in mortality (258). This is supported by a cohort of 23 Danish C282Y homozygotes who did not develop manifestations of disease after 25 years of follow-up (343).
2. A latent period should exist to permit the opportunity for screening and treatment before the development of morbidity and mortality. In addition, an acceptable treatment should be available and effective to those identified with the condition. Iron depletion by phlebotomy has been the standard of care for several decades. Although no randomized trials exist to support its use and ethical considerations will prevent any such studies in the future, phlebotomy appears to be an effective treatment when instituted early in the disease process. In particular, liver fibrosis appears to halt and in some cases improve (102).
3. A suitable screening test must be available for the condition. TS has been advocated as the most suitable test for HH screening. As discussed above, it has a reasonable sensitivity and can identify individuals prior to the onset of significant iron overload. An added benefit is the identification of iron deficiency and other disorders, such as chronic liver disease. The positive predictive value of genetic screening remains uncertain particularly for the H63D mutation, which confers only a small risk toward the development of iron overload.
4. The cost of screening should be reasonable. Analysis of cost effectiveness for serum iron indices indicates a very favorable cost compared to screening programs

for other conditions (344–349). Even though the cost of high-throughput genotyping has plummeted in the past few years, the cost of population-wide genetic testing would still be expensive (345). The combination of serum iron studies followed by genetic testing has been suggested as the most cost-effective approach (336).

5. The test must also be acceptable to the target population. Serum TS has been widely accepted in screening trials. Genetic testing may encounter significant resistance owing to legal, financial, and ethical concerns. However, genetic screening for HH appears to be well accepted (350–352).

Uncertainty surrounding screening for HH primarily concerns the natural history of HH and whom to treat. A systematic review for the US Preventive Services Task Force examined the burden of suffering and the potential of a preventative intervention (256). The conclusion of this analysis was that there remains insufficient evidence to confidently project the impact of, or estimate the benefit from, widespread or high-risk genetic screening for HH.

**101.3.1.10 Clinical Management.** The concept of repeat blood letting for treatment of HH was first studied in the 1950s (353). Treatment of HH with established hepatic iron overload involves iron depletion, nearly always by whole-blood phlebotomy (276,334). The importance of early treatment cannot be overemphasized. Treatment in the precirrhotic stage of HH can yield a normal life expectancy (101,102).

Every 1 mL of packed red blood cells contains ~1 mg of iron so that a 500-mL phlebotomy contains between 200 and 250 mg of iron (354). In adults, the initial phase of treatment involves rapid-sequence phlebotomy designed to eliminate excessive iron stores and minimize organ injury. Adults with severe iron loading usually tolerate the removal of 500 mL of blood once or twice each week until iron-limited erythropoiesis occurs (334). Iron depletion can be confirmed by the presence of slight anemia, decreased mean red cell volume (usually <75 fL), and a markedly decreased TS and serum ferritin concentration (<15% and <20 mg/L, respectively). The serum ferritin concentration usually normalizes before the TS (334,355). After initial iron depletion is accomplished by rapid-sequence phlebotomy, lifelong maintenance phlebotomy therapy is begun. Most patients require phlebotomy therapy at intervals of 2–6 months. The serum ferritin concentration can be measured each year to estimate body iron stores and to adjust the frequency of phlebotomies (334).

The results of vigorous phlebotomy therapy have only been studied on a large scale in older patients with HH (101,102,104). Symptoms due to congestive heart failure (356), diabetes mellitus (357), hypogonadism (358), and general malaise improve with phlebotomy treatments. Patients who are diagnosed and treated in

the precirrhotic stage have been shown to have a normal life expectancy. Cirrhotic patients have a shortened life expectancy and a high risk of liver cancer, even when complete iron deficiency is achieved (101,102). The effect of phlebotomy on lipid metabolism has shown no effect on blood glucose and total cholesterol, whereas triglyceride lowering is seen when ferritin and TSs are dropped (359). Unfortunately, as discussed above, some complications of HH have not shown significant improvement with phlebotomy, including arthropathy. These patients may develop osteoarthritis, severe enough to warrant surgical repair. Total ankle arthroplasty, for example, has been shown to be associated with a low risk of complication in HH with significant pain relief (360). Oral or intravenous iron chelation therapy is not generally recommended, but may be considered in cases in which phlebotomy cannot be tolerated.

A question frequently asked by pediatricians is what infant formula to recommend to families in which a proband has been identified with HH. Iron-fortified formula significantly protects against iron deficiency and its sequelae in child development. As the presentation of HH is relatively uncommon in children and because iron deficiency is such a prevalent problem with serious sequelae, an iron-fortified formula is recommended in such families when not breastfeeding.

Olsson and colleagues were unable to show any negative effects of generalized iron fortification of food on populations with a high prevalence of HH (361). It is generally recommended that some foods and iron supplements be avoided by patients with iron overload, such as iron-rich foods and vitamin C, which reportedly increase dietary iron absorption (160,362). At present, there are no data on the use of low-iron diets in the prevention or treatment of HH, and such diets may be impractical.

### 101.3.2 Juvenile Hemochromatosis

After the identification of the *HFE* gene, it was discovered that some causes of hemochromatosis were due to non-*HFE* mutations. JH or type 2 HH is an autosomal recessive disorder of early onset of iron overload resulting in cardiomyopathy, hypogonadism, and diabetes, presenting in the teens and early 20s (75,363,364). While once characterized as an early manifestation of classic HH (type 1), the clinical presentation, genetic linkage studies, and the most recent molecular discoveries show that JH is a distinct disease. JH is uncommon, yet the recent discoveries of hepcidin and hemojuvelin, the protein protagonists that cause hemochromatosis type 2b (HFE2b) and type 2a (HFE2a), respectively, have completely changed our understanding of iron homeostasis, HH, and related disorders.

**101.3.2.1 Clinical Features.** Clinical and pathologic descriptions of what is now known as JH, in contrast to classical type 1 adult-onset disease, date back well before molecular diagnoses became available. JH usually

presents before the age of 30. The pattern of organ involvement is similar in both HH and JH, except that JH patients have a more fulminant clinical course, especially as a result of hypogonadism and cardiomyopathy, which are more prominent and severe (174). In contrast to adults with HH, females and males are equally affected in JH (365).

Symptoms of hypogonadism are frequently chief complaints in JH (131,174,365,366), whereas they usually have less clinical relevance in HH (367). Hypogonadism, as manifested by secondary amenorrhea, diminished libido, loss of sexual hair, or impotence, is observed in 64% of patients under 30 years, compared to 30% of older patients (365). Autopsy studies in young patients demonstrate iron deposition in the pituitary, adrenal cortex, gonads, thyroid, and parathyroid glands (90,366,368–370). Compared to iron deposition in other tissues, gonadal iron accumulation in young patients is relatively small and is present predominantly in the blood vessel endothelium (366). The pathogenesis of hypogonadism appears to be identical in both age groups and is caused by the specific distribution pattern of excess iron accompanied by functional impairment of affected parenchymal cells (174,365,371). However, for reasons that remain unclear, younger patients are more frequently affected (365).

Cardiac dysfunction is the usual cause of death in untreated JH (131,174,366). The cardiac disorder has been characterized as a restrictive cardiomyopathy in appropriately examined younger patients (126,365,372). However, the frequency of cardiomyopathy in the younger group (58%) is greater than in the older group (35%) (365). Heart failure is extremely common in younger subjects, and symptoms may develop suddenly with rapid progression to death (100,366). Because there is a direct correlation between the severity of myocardial siderosis and cardiac dysfunction (373), young patients probably accumulate large amounts of iron in the myocardium (174). This is supported by autopsy studies where a substantial deposition of iron was found in the heart of a 21-year-old man with cardiac complications (374), and in a report where severe myocardial siderosis was found in German twins who died at ages 19 and 20 (174).

Hepatic involvement is present in 83% of young patients reported in the literature, and is significantly less than the 93% frequency reported for the over-30 age group (365). A postmortem examination of four young patients aged 19–28 showed heavy iron deposition in parenchymal liver cells and varying amounts of portal fibrosis (366). A nodular hepatic architecture was present in other young patients (366,375), and portal hypertension has also been described (376).

Both diabetes and arthritis are less prevalent in younger patients. The frequency of diabetes mellitus or glucose intolerance is only 34% in patients younger than 30 (365). There are reports of arthritis in young patients

(377,378), but in Lamon and colleagues' review of 52 young patients dating back to 1895, only 5 had symptoms of arthritis (365).

**101.3.2.2 Molecular Biology of JH.** The mouse models of hepcidin deficiency and overexpression inspired the search for mutations of a human gene that could cause or contribute to hemochromatosis. Two families with severe JH were reported by Roetto and colleagues (379). One family had a homozygous frameshift mutation and the other a homozygous premature stop (nonsense) mutation; both in the coding region of hepcidin. Since a genetic locus for JH was previously mapped to chromosome 1q (HFE2a), rare mutations of *HAMP* encoding hepcidin on 19q13.1 were assigned to the “HFE2b locus.”

The first genetic mapping of a JH locus was to chromosome 1q (originally called the “HFE2 locus” and later “HFE2a” after mutations of the hepcidin gene were found) preceding the discovery of the first JH gene, *HAMP* on 19q13.1, by several years (72,380). Thus *HAMP* was designated the “HFE2b locus” because it was discovered after the 1q locus. Discovery of the *HJV* gene (HFE2a) quickly followed *HAMP* (HFE2b). Papanikolaou and associates reported the positional cloning of the 1q locus associated with JH and the identification of a gene, *HJV*, crucial to iron metabolism, which they called hemojuvelin (75). Studies in Greek, Canadian, and French families indicated that a G-to-T variant at position 1284 in the *HJV* gene, resulting in a glycine320 to valine missense, was present in all three populations and accounted for two-thirds of the mutations. The hemojuvelin protein is also called Repulsive Guidance Molecule c (RGMc), a member of a three-gene family of RGMs. The other members of this family include RGMa and RGMb, proteins found in the nervous system. RGMc/*HJV* is expressed in skeletal muscle, cardiac myocytes, and hepatocytes. Initially, RGMc/*HJV* was identified as a novel transcript that was expressed during the differentiation of skeletal muscle (381). Subsequently, it has been shown to be involved in the regulation of hepcidin expression through its actions as a BMP coreceptor and that it can be regulated itself by maltriaptase (TMPRSS6).

**101.3.2.3 Management of JH.** Treatment in children is accomplished by initially removing 5–7 mL/kg of blood every 7–10 days (275). Phlebotomy is continued at this frequency until the iron overload is relieved and equilibrium reached, in which iron loss by phlebotomy matches intestinal absorption. Attainment of equilibrium status is signified by normal values for serum iron, ferritin, and TS. Once the goal of removing excess iron has been achieved, the frequency of phlebotomy can be reduced to once every 1–3 months, maintaining serum ferritin and TS within the low reference range for age. Hemoglobin levels and mean corpuscular volume (MCV) should also be monitored regularly because excessive phlebotomy results in anemia (276).

### 101.3.3 Neonatal Hemochromatosis

Neonatal hemochromatosis (MIM #231100) is a rare gestational condition characterized by iron accumulation in the liver and extrahepatic sites of the fetus, and sparing the cells of the reticuloendothelial system (reviewed in Knisely et al., 2003) (382). This pattern of iron deposition resembles that seen in classic adult-onset type 1 *HFE*-associated hemochromatosis (HH). Liver damage is extensive and frequently the dominant clinical feature. NH often results in late gestation fetal loss, or death within a few days of birth despite aggressive support. It is the most frequent cause of liver failure in newborns. The recurrence rate in sibships is greater than that predicted for simple Mendelian autosomal inheritance, but the etiology, inherited or acquired or both, remains unclear. The diagnosis is frequently overlooked until autopsy. Treatment remains inadequate.

**101.3.3.1 Clinical Features.** Clinical manifestations of NH begin prenatally, usually in the last trimester of pregnancy. Fetal losses in late gestation are common. Placental edema, fetal hydrops, edema, ascites, intrauterine growth retardation, and oligohydramnios are frequent complications, although polyhydramnios has been reported as well (383). Birth frequently occurs before term.

The dominant presenting feature in live born infants is that of acute liver failure. Liver disease is usually apparent within hours of birth, though in rare cases may manifest days to weeks after birth (384–386). Prominent features typical of acute liver failure include hypoglycemia, marked coagulopathy, hypoalbuminemia, and edema with or without ascites, and oliguria. Initial treatment almost always is for presumed sepsis or septic shock. Disseminated intravascular coagulation with increased fibrin split products may play a role in coagulopathy. Placental edema may be due to decreased oncotic pressure. Neonatal or fetal oliguria may be the result of hepato-renal syndrome, or rarely renal tubular dysgenesis (387). Mixed hyperbilirubinemia with elements of both conjugated and nonconjugated bilirubin results in jaundice during the first few postnatal days. This may be because of an increased bilirubin load from intravascular hemolysis and extravasated blood, or impaired hepatic bilirubin conjugation and excretion. Decreased serum alpha-1-antitrypsin, ceruloplasmin, and transferrin have been reported (383). While abnormal serum bile acid profiles have been reported, it is unclear if this represents a primary defect of bile acid synthesis, or a sequelae of severe hepatocellular disease (388,389). Serum amino transferase levels are disproportionately low for the degree of hepatic dysfunction, presumably due to the loss of functional hepatocyte mass. Serum alpha-fetoprotein levels are characteristically highly elevated, in the range of 100,000–600,000 ng/mL. Levels of this magnitude are almost exclusively seen in NH or hereditary tyrosinemia, and are much higher than those typically observed in viral or toxic hepatitis of the newborn.

**101.3.3.2 Etiology.** There are two main hypotheses concerning the etiology of NH: (1) fetal liver injury causes abnormal iron handling, and (2) abnormal iron handling by the placenta leads to hyperaccumulation of iron and to liver injury. Unlike classic adult-onset or JH, no genetic mutations have been associated with NH, and no locus has been identified by genetic linkage. The *HFE*-associated locus on 6p21.3 has been excluded by linkage analysis (390). Consequently, both hypotheses concerning the etiology of NH could be valid depending on the circumstances. For example, NH or iron-overload features have been reported with hereditary tyrosinemia (391,392), Down syndrome (393), tricho-hepato-entero syndrome (394), GRACILE syndrome (395), congenital cytomegalovirus (CMV) infection (396), and non-A non-B hepatitis (382). All of these cause liver injury, which presumably can impair iron handling (hypothesis 1 above), though they rarely are associated with iron overload and generally do not present as acute liver failure in the newborn.

Almost all of the molecular constituents of iron absorption and regulation that are active in the intestinal enterocyte have been described in the placental trophoblast. These include the transferrin receptor, FPN1, *HFE*, and hepcidin. The potential roles that abnormal iron handling within the placenta (hypothesis 2), abnormal fetoplacental, or maternoplacental interaction, may play in NH has not yet been determined, though there are some interesting data from animal studies. Mouse pups that constitutively overexpress hepcidin are born iron deficient suppressing transplacental iron flux into the fetus (397). In contrast, hepcidin knockout mouse pups develop iron overload several months after birth (398). While these models show that hepcidin is important in regulating placental iron flux, human NH is significantly different in that it begins sometime during gestation. Furthermore, while hepcidin mutations cause JH, no mutations of hepcidin or hemojuvelin (shown to regulate expression of hepcidin), identified in a neonate or mother, have been associated with NH; and cases of NH have not been described in classic HH or JH kindreds.

Interestingly, the observed recurrence rate of NH in sibships exceeds 75% (399). This is high for recessive or dominant inheritance. While no man has been reported to have fathered infants with NH with different mothers, several kindreds have been described in which a woman has borne infants with NH to different fathers (400,401). This suggests that some cases of NH may be caused by gonadal mosaicism for new and dominant mutations lethal in spermatogenesis but not oogenesis, or mitochondrial disease inherited through the mother, or maternal transmission of an imprinted gene.

The high recurrence rate in sibships is also compatible with an acquired and persistent maternal factor reminiscent of gestational disease such as hydrops fetalis caused by Rh incompatibility and alloimmune thrombocytopenia. Such a factor in NH could be an antibody directed against a fetal or placental antigen involved in iron

handling (382,402). Fetal liver injury secondary to an alloimmune process, as opposed to a primary derangement of iron metabolism, has become increasingly favored as the primary cause of NH due to the recent reports of successful treatment of at-risk pregnancies (see treatment below) as well as the emergence of evidence in NH cases supporting an immune-based mechanism of hepatic injury (403,404).

**101.3.3.3 Treatment and Outcome.** A number of management strategies and treatments have been devised for NH, but regardless the overall prognosis remains poor (382,405). These include preterm delivery, a cocktail of antioxidants and iron chelators, orthotopic liver transplantation, and maternal intravenous gamma globulin (IVIG) infusions. IVIG treatment was devised on the theory that NH is an alloimmune gestational disorder. Whittington and Kelly reported results based on 48 women who previously had children with NH (406). The gestational histories of these women were remarkable in that of the 44 healthy babies delivered, 42 occurred prior to the index case. Following the index cases, there were 21 gestations by 13 women of which 19 resulted in NH, consistent with previous reports of high NH recurrence. Fifty-five subsequent gestations were treated with weekly IVIG infusions beginning at the 18th week of gestation. Of these, 53 pregnancies resulted in “good outcomes,” which is a marked improvement compared to the gestational histories of these mothers. Of the 41 infants who had measurements of serum ferritin and alfa fetoprotein (AFP), 29 babies showed elevations suggesting involvement of NH, but none had evidence of liver disease. Nine infants were treated with chelation/antioxidants. Additional case reports have suggested success with this approach in at-risk pregnancies as well as for the use of exchange transfusion for treatment of NH (407–409).

### 101.3.4 Atransferrinemia

Atransferrinemia (MIM #209300) is an extremely rare recessive disorder caused by the absence—or, in the case of hypotransferrinemia, severe deficiency—of the circulating iron transport molecule transferrin. To date, only 12 cases have been reported in the literature. (410–412). Transferrin is a glycoprotein with a molecular weight of 75,000–80,000; ~6% is carbohydrate (413). Transferrin is the major iron transport molecule of the circulation and the transferrin gene is part of a larger family whose members include p97, a membrane protein expressed in human melanoma cells and lactoferrin, which is the major iron-binding protein in milk. Interestingly, the genes for all three of these products are located on chromosome 3. Because 80% and 90% of transferrin traffic is directed to normoblasts for hemoglobin synthesis (3), the most striking clinical consequences of transferrin deficiency are due to the failure of hemoglobin synthesis and anemia.

**101.3.4.1 Clinical Features.** In 1961, Heilmeyer and colleagues described the first reported case in a girl who presented with severe hypochromic anemia at the age of four months (414). Since then, 11 other cases have been reported, with age at diagnosis ranging from birth to 20 years. In several cases, severe hypochromic microcytic anemia was found, with hemoglobin concentrations as low as 3.2 mg/dL (415). Evidence of iron overload in the liver and reticuloendothelial system was detected at autopsy or by liver biopsy in at least four of these cases, and elevated ferritin levels have been reported in others. In the case described by Heilmeyer et al., the patient died from cardiac failure, presumably due to severe hemosiderosis of the heart, which was found at autopsy (414). The patient reported by Goya and coworkers presented late, at the age of 7 following an acute febrile illness that was treated by chloramphenicol (416). In addition to anemia, this patient also had developmental and growth delay that persisted for a period of 5 years after presentation. Subsequently, he had significant catch-up growth (417). This recovery correlated with a rise in transferrin levels from below 10 mg/dL to around 20 mg/dL suggesting that symptoms are only apparent at transferrin concentrations below 10 mg/dL.

**101.3.4.2 Genetics.** In all cases, the mode of inheritance was presumed to be autosomal recessive. Hayashi and colleagues (417) restudied the family reported by Goya and colleagues (416) and found a small amount of a transferrin variant detected by isoelectric focusing gels in the proband and two of his siblings, although only the proband was symptomatic. The authors suggested that this patient represented a compound heterozygote consisting of a variant allele transmitted by the father and shared by two siblings, and a null allele inherited from the mother.

In some cases, affected individuals have been suspected of being heterozygous for a null allele and a hypomorphic variant accounting for a relatively mild course and/or a later onset of disease. For example, small amounts of transferrin were detectable by isoelectric focusing and anemia was first noted at age 7 in the patient studied by Hayashi and colleagues (417). Genetic characterization suggested that this individual carried both a missense allele (G1180A resulting in E394K) and a second undetected mutation located outside of exons or near splice sites (418). Genetic mutations have been reported in four other cases. Compound heterozygosity (G1429C resulting in A477P and a frameshift in exon 5 resulting in a nonsense mutation) was reported in a patient with onset of manifestations at age 20 (410). Cell lines established from the second known case of atransferrinemia, in which the onset of symptoms occurred during infancy, were homozygous for the missense mutation G229A (resulting in D77N) (419). Aslan et al. reported a C137Y mutation in a 4-month-old girl from Turkey (411). In the case reported by Chen et al., a G502C mutation was detected by sequencing in a 10-year-old boy (412). In

addition, a large number of transferrin alleles have been described that do not result in symptoms and which therefore represent polymorphic variants (420).

**101.3.4.3 Diagnosis and Differential Diagnosis.** The diagnosis is based on the assay of transferrin by nephelometry or immunoassay. Normal serum values range between 2.0 and 4.0 g/L (421). Congenital hypotransferrinemia must be distinguished from acquired hypotransferrinemia, which can be found in the setting of liver disease, nephropathies, enteropathies, inflammatory diseases, and malignancies (416). Atransferrinemia is exceedingly rare except in the genetic disorder.

**101.3.4.4 Management.** Goya and others (416,422) reported treatment with purified iron-free human transferrin, although its availability and cost may be prohibitive. The patient reported by Goya (an 8-year-old male) received 2 g of apotransferrin (9.8% protein in normal saline) in three doses over 16 days, resulting in an increase of hemoglobin concentration from 6.4 g/dL to more than 10 g/dL. The patient required an additional 1 g infusion of transferrin after 3 months and a third dose after 6 months, although the response was less marked than after the first infusion. At age 10, his infusion dosage was increased to 2 g, which he received approximately every 6 months. At this dose, his hemoglobin concentration remained near 10 mg/dL (417). Fresh frozen plasma transfusion has also been performed, although the quantity of transferrin infused is difficult to assess in these cases. Because iron overload has been reported for all surviving patients with atransferrinemia, whole blood or red cell transfusions should be avoided and iron chelators should be considered for patients demonstrating signs of iron overload.

## 101.4 OTHER DISORDERS RESULTING IN DERANGEMENTS OF IRON HANDLING

### 101.4.1 Connection between Disorders of Iron Utilization and Iron Absorption

Many diseases result in abnormalities of iron handling or deposition, although not all are due to a primary derangement of molecules normally involved with iron metabolism. The largest category of such disorders is anemia due to a variety of defects of hemoglobin synthesis or red blood cell architecture. These disorders are associated with secondary iron overload because they cause an accelerated rate of hematopoiesis. This leads to increased intestinal iron absorption that may be compounded by the need for transfusion therapy. Other causes of secondary iron overload include chronic liver disease due to a variety of causes, portacaval shunting, and chronic hemodialysis. However, at least two disorders—iron-refractory iron-deficient anemia and hypochromic microcytic anemia with hepatic iron overload—demonstrate the molecular network connecting the iron needs for red blood cell production and systemic iron absorption. Moreover,

conditions such as African iron overload suggest that there are genetic influences on the control of iron metabolism that remain to be identified.

### 101.4.2 Iron-Refractory Iron-Deficient Anemia

In 1981, Buchanan and Sheehan suggested that a form of microcytic anemia was due to a primary derangement of iron metabolism (423). Three siblings were demonstrated to have malabsorption of medicinal iron and responded partially to intramuscular iron dextran. Finberg et al. referred to this phenotype as iron-refractory iron-deficiency anemia (IRIDA, MIM #206200) (424). IRIDA is characterized by congenital hypochromic, microcytic anemia with low mean corpuscular erythrocyte volume, low TS, and abnormal iron absorption that is unresponsive to oral iron and partially responsive to parenteral iron. Several authors have reported cases with these characteristics. Finberg et al. noted that whereas urinary levels of hepcidin (MIM #606464) are typically undetectable in individuals with iron deficiency, hepcidin-creatinine ratios were within or above the normal range in IRIDA cases. Mutations in the *TMPRSS6* gene have been found in kindreds with IRIDA (424,425). *TMPRSS6* encodes a type II transmembrane serine protease expressed primarily in liver and orthologous mutations in the mouse result in anemia as a result of defective dietary iron uptake. It has been suggested that *TMPRSS6* is a negative regulator of hepcidin transcription.

### 101.4.3 Hypochromic Microcytic Anemia with Iron Overload

In 1981, Bannerman suggested that some human iron handling disorders may be analogous to that of the *mk* mouse, which exhibits iron deficiency and severe microcytic anemia as a result of defects in the *Slc11A2* gene. *Slc11A2* encodes a divalent metal ion transporter responsible for absorption of ferrous iron in the duodenum (426). It is also expressed in the erythroblast where it may facilitate absorption of transferrin-bound iron into the cytoplasm. A patient with a mutation within the human homolog of this gene, *SLC11A2* (*DMT1*), has been described (427). The patient had a homozygous mutation in the ultimate nucleotide of exon 12 (G1285C) resulting in a preferential skipping of exon 12 during processing newly transcribed RNA as well as an E399D missense mutation. Clinically, this patient presented in infancy with microcytic anemia and subsequently developed liver dysfunction with iron overload characterized by increased iron deposition in both Kupffer cells and hepatocytes demonstrated on liver biopsy at the age of 19 (Hypochromic microcytic anemia with iron overload, MIM #206100). Additional reports of patients with mutations in the *SLC11A2* gene (428) presenting with hypochromic, microcytic anemia and severe hepatic

iron overload suggest that unlike the rodent model, the *SLC11A2* mutations in humans result in defective iron utilization in the reticulocyte but does not eliminate iron absorption from the gut.

#### 101.4.4 African Iron Overload

Other diseases have been reported that may result from primary abnormalities of iron metabolism. The prevalence of iron overload in certain populations of Africa (African iron overload, formerly Bantu siderosis, MIM #601195) has been felt to reflect the consumption of large quantities of home-brewed beer that is extremely high in iron content (429). These patients demonstrate panlobar iron deposition in the liver, with marked deposition in the Kupffer cells. This distribution is in contrast to patients with HH, who predominantly exhibit a periportal pattern of iron deposition that affects mainly hepatocytes, with sparing of the Kupffer cells. A genetic predisposition for development of systemic iron overload when exposed to high dietary iron intake in Africans has been proposed (430,431) although linkage with HFE1 on chromosome 6 has been excluded (432). There have been recent reports of associations between iron overload in Africans and polymorphic variants in other genes involved in iron metabolism including *SLC11A3* (FPN1 or HFE4) and *CYBRD1* (encoding a putative plasma membrane diheme protein, expressed on the apical duodenal membrane, with ferric reductase activity) (433,434). However, the relationship between polymorphisms in these genes and development of iron overload is complex and the risk to carriers of these variants for developing disease from iron overloading is uncertain.

#### 101.4.5 Primary Defects of Iron Handling as a Cause of Neurological Disease

In addition to the five genes for which variants have been determined to cause iron overload syndromes (Table 101-1), a number of genes whose roles include support of systemic, cellular, or intracellular iron homeostasis have been described in recent years. Variants of these genes have been described in a number of degenerative neurological disorders suggesting a role of abnormal iron metabolism or handling in their pathogenesis, consistent with observations in diseases of iron abnormalities but often local in certain cells or tissues. These include Friedreich ataxia (MIM #229300), and X-linked sideroblastic anemia and spinocerebellar ataxia (MIM #301310), aceruloplasminemia (MIM #604290), and neuroferritinopathy, a form of neurodegeneration with brain iron accumulation (NBIA) due to mutations in L-ferritin.

#### 101.4.6 Friedreich Ataxia

Friedreich ataxia is a rare autosomal recessive inherited neurological ataxia, most often caused by a GAA-repeat

expansion in the *FRDA* gene, with a few cases (2%) caused by *FRDA* point mutations (435), which encodes frataxin (MIM #229300) (see Chapter 118). Of interest to iron metabolism is that frataxin is a mitochondrial protein with high homology to YFH1, a yeast protein involved in iron homeostasis and respiratory function (264). Deficiency of YFH1 in yeast results in mitochondrial iron accumulation, whereas *FRDA* mutations in humans also result in increased mitochondrial iron (436,437). Frataxin deficiency also results in increased sensitivity to oxidative stress, decreased activities of mitochondrial iron-sulfur proteins, decreased mitochondrial DNA content, and impaired cellular respiration (438,439). Potential functional roles of frataxin include iron-sulfur cluster assembly (440), maturation of proteins containing such clusters (441), and mitochondrial iron storage (442). These findings suggest that frataxin is required for mitochondrial iron metabolism and that frataxin deficiency leads to iron accumulation, oxidative stress, and mitochondrial dysfunction. Idebenone, coenzyme Q<sub>10</sub>, and other antioxidants have been suggested as treatments (362,443). Treatment with deferiprone, a “reversed” siderophore, has been suggested as mechanism for iron redistribution and an open-label trial has suggested some benefit (444,445).

#### 101.4.7 X-Linked Sideroblastic Anemia with Ataxia

X-linked sideroblastic anemia with ataxia (XLSA/A, MIM #300751) is a rare disorder characterized by a mild X-linked sideroblastic anemia, elevated free erythrocyte protoporphyrin levels, mitochondrial iron accumulation, and nonprogressive cerebellar ataxia with onset early in childhood. Allikmets et al. demonstrated a sequence variant (T1200G) in the *ABCB7* gene resulting in the missense mutation, I400M in a three generational pedigree with four affected males (446). The *ABCB7* gene encodes an ATP-binding cassette transporter localized to the inner mitochondrial membrane and is believed to participate in iron-sulfur protein maturation by supplying iron-sulfur clusters to the cytosol; disruption of this process in XLSA/A leads to mitochondrial iron loading and mitochondrial dysfunction (447).

#### 101.4.8 Aceruloplasminemia

Ceruloplasmin is a copper-dependent ferroxidase involved in the oxidation of ferrous iron to ferric iron, and its deficiency is thought to interfere with the release of iron from cells into the plasma as transferrin (448). Several mutations have been described in the ceruloplasmin gene in aceruloplasminemia (MIM #604290), all of which lead to truncation of the carboxyl terminal portion of the protein, which is known to be essential for the coordination of a trinuclear copper cluster (reviewed by Harris et al., 1998) (449). The clinical features of the

disease are marked by iron overload of the liver parenchyma, pancreatic islet cells and brain, especially the retina and basal ganglia, resulting in diabetes and neurological symptoms (450–452). Treatment with desferoxamine has been advocated (453).

### 101.4.9 Neuroferritinopathy

Intracellular storage of iron occurs mainly in the form of iron–protein complexes. Ferritin is the major intracellular iron storage protein in all organisms. Ferritin consists of H and L subunits that form a 24 subunit shell enclosing variable amounts of ferric hydroxide phosphate complexes. The synthesis of ferritin subunits is regulated at the translational level by iron through interaction with the cytoplasmic IRP or IRE-binding protein. As discussed above, the IRE is a conserved nucleotide motif present in the 5′ noncoding region of all ferritin mRNAs. During periods of low cellular iron, the IRP binds the IRE preventing translation of ferritin subunits.

A point mutation (A49U) located in the IRE motif of H-ferritin mRNA was found in members of a Japanese family with iron overload inherited as an autosomal dominant trait (454). This mutation caused an increase in affinity of IRP for the IRE of H-ferritin mRNA containing the A49U variant, as demonstrated *in vitro* by Kato et al., which presumably resulted in decreased amounts of H-subunit synthesis and a decrease of intracellular iron storage capacity as ferritin complexes leading to pathological iron deposition in tissues (454).

A mutation in the L-ferritin subunit gene (*ins460A*) was described by Curtis et al. in patients with dominantly inherited extrapyramidal dysfunction and degenerative changes of the basal ganglia with onset in the fifth to sixth decade of life (neuroferritinopathy, a form of NBIA, MIM #606159) (127). Accumulation of iron was demonstrated in the neurons of affected individuals especially in the globus pallidus, as well as in the forebrain and cerebellum. The L-ferritin mutation *ins460A* results in disruption of the C-terminal 22 amino acids of the protein, which the authors speculate may destabilize the L-ferritin subunit altering the properties of the ferritin complex causing release of free iron into the cytosol. A second family was reported by Chinnery et al. (455).

### 101.4.10 Hereditary Hyperferritinemia–Cataract Syndrome

Other mutations in the ferritin light-chain IRE have been found to cause the hereditary hyperferritinemia–cataract syndrome (HHCS, MIM #600886). This autosomal dominant disorder is characterized by elevated serum ferritin and nuclear cataract (456,457). Most mutations described to date have been point mutations (457–461), although a deletion has also been reported (462). The pathophysiology of this disorder involves the dysregulation of L-ferritin expression, resulting from the

destabilization of the IRE or the disruption of IRP–IRE recognition (463). Although the pathophysiology for this disorder involves regulatory control of a molecule important in iron metabolism, patients with HHCS are neither iron overloaded nor deficient.

### 101.4.11 Other Neurological Disorders Associated with Abnormal Iron Handling

Local iron overload, deposition, or deficiency has also been a finding in the context of certain Mendelian disorders as well as other complex genetic diseases involving the central nervous system. It is less clear in these cases whether abnormal iron handling is a primary etiologic event or a secondary phenomenon due to cellular injury from other mechanisms (464). Pantothenate kinase-associated neurodegeneration (PKAN, MIM #234200) and disorders associated with PLA2G6 mutations may fall into this category. Iron overload in particular brain regions has also been reported in Parkinson’s disease (465,466) and Alzheimer’s disease (467), while brain iron deficiency has been associated with restless legs syndrome (RLS) (468) and attention-deficit hyperactivity disorder (469).

### 101.4.12 Pantothenate Kinase-Associated Neurodegeneration

PKAN is a disorder associated with iron deposits in the basal ganglia (470–472), characterized by progressive dystonia, dysarthria, and rigidity beginning in childhood. Differential diagnosis includes other NBIA disorders such as PLA2G6-associated neurodegeneration, neuroferritinemia, and aceruloplasminemia. Diagnosis can be made with the aid of MRI, which often shows decreased signal intensity in T2-weighted images, compatible with iron deposition, and with a small central area of hyperintensity (“eye-of-the-tiger” sign) (473). Zhou et al., using positional cloning methodology based on classical linkage analysis, identified mutations in the coding sequence of a gene called *PANK2* that has homology to murine pantothenate kinase-1 (474). *PANK2* is one of four pantothenate kinases, but it is the only one localized to mitochondria (475). A description of classic disease (characterized by early onset with rapid progression) versus atypical disease (later onset with slow progression) was made (476). In their study of 98 families, Haflick et al. identified mutations in *PANK2* in all families with classic disease (49/49) but in only 35% of families with atypical disease (17/49) (476). Null mutations (alleles predicting protein truncation) were prevalent in individuals with classical disease (36/92 alleles) but rare among those with atypical disease (2/31 alleles). This suggests that residual enzyme activity is preserved in some *PANK2* variants arising from missense mutations possibly accounting for a less aggressive clinical presentation. Patients with atypical disease who had *PANK2*

mutations were also more likely to have speech-related and psychiatric symptoms than patients with classic disease or mutation-negative patients with atypical disease. All patients whose clinical picture included the eye-of-the-tiger sign were found to carry *PANK2* mutations, while conversely, those patients without this sign were all mutation negative. These authors report that the G1231A mutation (resulting in G411R) was common in their patient series and may represent a founder mutation of European ancestry; interestingly this mutation may be semidominant. Mutations in *PANK2* have also been reported in individuals with HARP (Hypoprebetalipoproteinemia, acanthocytosis, and retinitis pigmentosa; MIM #607236) syndrome (477,478). This syndrome also presents with the eye-of-the-tiger sign. Treatment is primarily aimed at palliation and is often temporally limited in terms of clinical benefit (479). Supplemental pantothenate (vitamin B<sub>5</sub>) has been proposed as a potential therapy for patients carrying *PANK2* mutations retaining partial enzyme activity, as has the chelating agent deferiprone.

#### 101.4.13 *PLA2G6*-Associated Neurodegeneration and Other Non-PKAN Forms of NBIA

The presentation of disorders caused by mutations in the *PLA2G6* gene is clinically heterogeneous and includes a spectrum of progressive psychomotor deficits, mostly pyramidal but partially overlapping those of PKAN, which range from neonatal infantile neuroaxonal dystrophy (INAD, NBIA2A, MIM #256600) to mid-childhood (atypical neuroaxonal dystrophy, NBIA2B, MIM #610217) in onset. Cerebral atrophy and brain iron accumulation, usually in the globus pallidus, are typical findings, although not all affected individuals exhibit accumulations of brain iron. Mutations in *PLA2G6* have been described in a variety of kindreds within this spectrum (480,481). *PLA2G6* encodes a cytosolic calcium-independent phospholipase A2. The iPLA2 enzymes catalyze the release of arachidonic acid from membrane phospholipids and are critical in cell membrane homeostasis. However, as molecular testing has increased, cases have been reported of patients with later onset and slower progression without high brain iron (482,483). Mutations in addition to those described above have been described in at least three other genes for various cases of NBIA including *fatty acid-2 hydroxylase* (484), *lysosomal type 5 P-type ATPase* (485), and *C2orf37* (479,486).

## Biographies

**Kaveh Hoda, MD** is currently a fellow in the Division of Gastroenterology and Hepatology at the University of California Davis Medical Center. Dr Hoda studied Molecular Cell Biology, with an emphasis in genetics, at the University of California Berkeley and graduated Summa Cum Laude before attending medical school at the University of California Davis. He completed his Internal Medicine Residency at the Santa Clara Valley Medical Center, where he also served as the chief resident. He studied liver transplantation and hepatology for one year at the California Pacific Medical Center prior to returning to UC Davis for fellowship training. His research and publications include Hepatitis B and Hemochromatosis.

**Tom Chu, MD, PhD** is a clinical director at Roche and currently serves as Biomarker Expert for Virology. In this role, he is responsible for biomarker strategy in early drug development. He received his MD and PhD degrees from Washington University in St. Louis and residency and fellowship training in Pediatrics and Medical Genetics at Yale University. He has held academic appointments at Yale as Associate Research Scientist in Genetics and the University of California, San Diego, as assistant professor of Pediatrics. His scientific work has included the discovery and characterization of genes in the human major histocompatibility complex.

**Jeffrey R Gruen, MD** is Professor of Pediatrics, Genetics, and Investigative Medicine at the Yale University School of Medicine and the Yale Child Health Research Center. He is a graduate of the Tulane University School of Medicine, and completed residency in Pediatrics at Yale-New Haven Hospital. He completed his fellowship training in Neonatal Medicine at Yale Medical School, while undertaking scientific training in molecular genetics. During fellowship, Dr Gruen mapped the short arm of human chromosome 6 including the major histocompatibility complex and hemochromatosis locus on 6p21.3. Later, he shifted his mapping studies further up chromosome 6 to the DYX2 locus for dyslexia, where he identified *DCDC2* as an important gene for dyslexia. Currently, the main focus of his lab is the genetics of language acquisition, reading, and dyslexia. In addition to mentoring graduate students and postdocs in Genetics, Dr. Gruen continues to attend as a neonatologist in the Newborn Intensive Care Unit of the Children's Hospital at Yale-New Haven.

**Christopher L Bowlus, MD** is Professor of Medicine and serves as the Program Director for the Gastroenterology Training Program at the University of California Davis School of Medicine. Dr Bowlus received his medical degree from St Louis University School of Medicine, completed a residency in Internal Medicine at the University of California Davis, and went on to complete fellowship training in gastroenterology at Yale University School of Medicine. Since 1998, he has been on faculty within the Department of Internal Medicine at the University of California Davis. His interests include the study of hereditary hemochromatosis and the interactions of iron overload on other forms of chronic liver disease.

## Mucopolysaccharidoses

*J Ed Wraith*Pediatric Inherited Metabolic Medicine, Genetic Medicine, St. Mary's Hospital,  
Manchester, UK

This article is a revision of the previous edition article by Jürgen Spranger, volume 3, pp 2403–2412, © 2007, Elsevier Ltd.

## 102.1 GENERAL ASPECTS

### 102.1.1 Definition

The mucopolysaccharidoses (MPSs) are a family of disorders due to inherited defects in the catabolism of sulfated components of connective tissue known as glycosaminoglycans (GAGs). GAGs are long-chain complex carbohydrates consisting of a variety of uronic acids, amino sugars, and neutral sugars. They are usually linked to proteins to form proteoglycans. Proteoglycans are the major constituent of the ground substance of connective tissue and they are also present in mitochondria and nuclear and cell membranes. The major GAGs are chondroitin-4-sulfate (C4S), chondroitin-6-sulfate (C6S), heparan sulfate (HS), dermatan sulfate (DS), keratan sulfate (KS), and hyaluronic acid (HA).

### 102.1.2 Etiology

The genes for all MPSs have been cloned ([Table 102-1](#)), and numerous, mostly private, mutations have been identified. Inheritance is autosomal recessive in all MPSs, except MPS type II (MPS II), which is X-linked.

### 102.1.3 Pathogenesis

The MPSs are degradation defects of GAGs. GAGs are broken down by the sequential action of lysosomal enzymes leading to a stepwise shortening of the GAG chain (for example see [Figure 102-1](#) and Reference (1)). The absent activity of a lysosomal enzyme results in the gradual accumulation of partially degraded GAG molecules in lysosomes. Distended lysosomes accumulate in the cell and by an unknown mechanism interfere with normal cell function.

Different MPSs are caused by different enzyme deficiencies leading to the accumulation of biochemically different GAG degradation products. As a general rule, the impaired degradation of HS is more closely associated

with mental deficiency and the impaired degradation of DS, chondroitin sulfates, and KS with mesenchymal abnormalities. Some of the salient features of the MPSs are summarized in [Table 102-1](#).

Some clinical manifestations of the MPS, such as coarse facial features, thick skin, corneal clouding, and upper airway obstruction, can be regarded as the direct expression of GAG accumulation in tissue. Others, such as mental retardation, growth deficiency, and skeletal dysplasia, are the result of defective cell function. Joint contractures and hernias point to an interference of accumulated GAGs with other metabolic substances such as collagen or fibronectin. Cardiac disease may be the result of the impaired elastogenesis which has been demonstrated in MPS I (Hurler disease). It appears that the accumulation of the GAG DS (but not HS) is linked to impaired elastic fiber assembly (2) and upregulation of elastases (demonstrated in animal models) secondary to cytokine activation may be important (3). The Toll-like receptor 4 pathway may have an important role in the evolution of bone and joint disease in MPSs and therefore treatments that inhibit the production of inflammatory cytokines may have a role to play in management (4,5).

### 102.1.4 Incidence

The crude cumulative rate for all types of MPSs is around 3.5 in 100,000 live births (6). There are striking variations in the frequency of various forms of MPSs in different populations. For example in the Irish Travelling community, Hurler syndrome is exceptionally common with a birth incidence of one in 371 and a carrier frequency of one in 10 (7).

### 102.1.5 Diagnosis

Although technically possible (8,9) and supported by patients and families (10) newborn screening for MPS disease is not yet available at a population level. Initial diagnosis depends on clinical acumen.

TABLE 102-1 MPS Enzyme Deficiency, Genetics and Clinical Features						
Disease	Enzyme Deficiency	Storage Material	Chromosome Location	Gene (OMIM Id)	Gene Mutations	Main Clinical Features
MPS						
MPS I (Hurler, Scheie, Hurler/Scheie)	Iduronidase (EC 3.2.1.176)	DS, HS	4p16.3	<i>IDUA</i> (252800)	W402X, Q70X plus many others	HSM, CNS, SD, DYS, OPH, CAR
MPS II (Hunter)	Iduronate-2-sulfatase (EC 3.1.6.13)	DS, HS	Xq27–28	<i>IDS</i> (300823)	No common mutations	HSM, CNS, SD, DYS, OPH, CAR, SK
MPS III (Sanfilippo)						
IIIA	Heparan-N-sulfatase (EC 3.10.1.1)	HS	17q25.3	<i>HSS</i> (605270)	R245H, R74C and many others	CNS, SD (+/–), DYS (+/–)
IIIB	N-acetyl-glucosaminidase (EC 3.2.1.50)	HS	17q21.1	<i>NAGLU</i> (609701)	No common mutations	CNS, SD (+/–), DYS (+/–)
IIIC	Acetyl CoA glucosamine N-acetyl transferase (EC 2.3.1.3)	HS	8p11.1	<i>HGSNAT</i> (610453)	No common mutations	CNS, SD (+/–) DYS (+/–)
IIID	N-acetyl-glucosamine-6-sulfatase (EC 3.1.6.14)	HS	12q14	<i>GNS</i> (607664)	Very few patients studied	CNS, SD(+/–), DYS (+/–)
MPS IV (Morquio)						
IVA	Galactose-6-sulfatase (EC 3.1.6.4)	KS	16q24	<i>GALNS</i> (612222)	I113F (UK and Ireland)	SD, CAR, OPH (+/–)
IVB	β-Galactosidase (EC 3.2.1.23)	KS	3p21-pter	<i>GLB1</i> (611458)	No common mutations	SD, CAR
MPS V	No longer used formerly Scheie disease					
MPS VI (Maroteaux–Lamy)	Galactosamine-4-sulfatase (EC 3.1.6.12)	DS	5q13–q14	<i>ARSB</i> (611542)	No common mutations	HSM, SD, DYS, OPH, CAR
MPS VII (Sly)	β-Glucuronidase (EC 3.2.1.31)	HS, DS	7q21.1–q22	<i>GUSB</i> (611499)	Very few patients studied	HF, HSM, CNS, SD, OPH, CAR
MPS VIII	No longer used					
MPS IX	Hyaluronidase (EC 3.2.1.35)	HA	3p21.3	<i>HYAL1</i> (607071)	Very few patients studied	U/K

Abbreviations: CAR, cardiac disease; CNS, regression; DS, dermatan sulfate; HS, heparan sulfate; KS, keratan sulfate; HA, hyaluronic acid; SA, sialic acid; DYS, dysmorphic appearance; HSM, hepatosplenomegaly; OPH, eye signs—corneal clouding; SD, dysostosis multiplex; SK, dermatological signs; WBC, white blood cell. (+/–), sign not always present or mild.

1. Low activity in CVB—caution re: contamination with maternal decidua.
2. Always do fetal sexing as some unaffected female fetuses will have very low enzyme results.
3. Difficult because of cross-reactivity from other sulfatases.

The MPS disorders tend to present in one of three ways:

- (1) As a dysmorphic syndrome (MPS IH, MPS II, MPS VI) often with early onset middle ear disease, deafness or upper airways obstruction
- (2) With learning difficulties, behavioral disturbance and dementia and mild somatic abnormalities (MPS III)
- (3) As a severe bone dysplasia (MPS IV)

Although initial medical contact is likely to be with the family physician or primary care practitioner it is unlikely that the diagnosis of these rare disorders will be suspected by these colleagues. Most will have never seen an MPS patient before in their clinical practice. Most diagnoses are made by metabolic physicians, clinical geneticists or general pediatricians. Other colleagues often have an opportunity to make an early clinical diagnosis of some MPS subtypes. This includes orthopedic surgeons (11) and otolaryngologists (12) in severe MPS I, II, IV or VI. In more attenuated variants (e.g. MPS I,

Scheie disease) rheumatologists may play a critical role in early diagnosis (13).

The first step in laboratory diagnosis is the analysis of urinary GAGs. A number of different methods exist for this screening test ranging from simple “spot” tests (that tend to be inaccurate and prone to false negative results (14)) to sophisticated analytical methods involving mass spectrometry (which are not universally available (15,16)). The most commonly available, reliable, method combines a quantitative measurement of total urinary uronic acid following precipitation with a dye (commonly dimethyl methylene blue) (17) with qualitative analysis of the species of GAG in the extracted sample by either one- or two-dimensional electrophoresis (18). It is important to stress that neither of these methods can diagnose a specific MPS disorder but an abnormal test does indicate that an MPS disorder is likely to be responsible for the patient’s symptoms. The pattern of GAG excretion seen on electrophoresis guides the clinician toward the

**FIGURE 102-1** The catabolism of dermatan, heparan, and keratan sulfate.

FIGURE 102-1—cont'd

appropriate enzyme analyses necessary to confirm the diagnosis (Table 102-1).

In positive cases, an enzyme diagnosis can be followed by specific mutation analysis in all of the MPS disorders.

Prenatal diagnosis is also possible for all MPS disorders. This is still often done by enzyme assay on uncultured chorionic villus biopsy (CVB) material but it is essential to combine this with fetal sexing in MPS II (Hunter syndrome) where some female carriers may have very low enzyme activities (19). Where the DNA mutation in an index case or family is known, prenatal testing can be performed by directly looking for the disease causing mutation in DNA extracted from a CVB sample.

For some families preimplantation genetic diagnosis is possible, although this is not universally available (20,21).

### 102.1.6 Dyostosis Multiplex

The skeletal abnormalities associated with MPSs are known as dysostosis multiplex (DM). These are progressive changes seen most floridly in the severe forms of MPS I (Hurler syndrome) and MPS VI (Maroteaux-Lamy syndrome). Patients with MPS II usually have less severe skeletal involvement although in most patients it remains significant whilst patients with MPS III (Sanfilippo syndrome) usually have very mild skeletal involvement.

FIGURE 102-1—cont'd

Patients with MPS IV (Morquio syndrome) have a very distinct skeletal dysplasia characterized by platyspondyly and this will be discussed further in [Section 102.8](#).

The major features of DM are a large skull with a deep, elongated, J-shaped sella, oar-like ribs, deformed, hook-shaped lower thoracic and upper lumbar vertebrae, pelvic dysplasia, shortened tubular bones with expanded diaphyses, and dysplastic epiphyses ([Figures 102-2 to 102-9](#)).

For a comprehensive review of DM the reader is guided to [Reference \(22\)](#).

## 102.2 MUCOPOLYSACCHARIDOSIS I (IH HURLER, IS SCHEIE AND IH/S HURLER-SCHEIE DISEASE)

MPS I is caused by a deficiency of the lysosomal hydrolase  $\alpha$ -L-iduronidase, an enzyme that removes terminal iduronic acid residues during the sequential degradation of dermatan (DS) and heparan sulfate (HS). As a consequence, DS and HS accumulate and interfere with cellular function (by an unknown mechanism) leading to a chronic and progressive multisystem disease. In addition, DS and HS are excreted into the urine in excess ([Table 102-1](#)).

In the United Kingdom, the birth prevalence for MPS I is 1.07/100,000 births with a prevalence of the subtypes of MPS I calculated as 0.76/100,000 (Hurler), 0.24/100,000 (Hurler/Scheie) and 0.07/100,000 (Scheie) ([23](#)).

### 102.2.1 Mucopolysaccharidosis IH (Hurler Disease)

MPS IH serves as a model for all of the other MPS disorders as affected children exhibit almost the full range of effects that can occur from abnormal GAG storage. Affected infants are normal at birth and appear to develop normally for the first few months of life although there does appear to be an increased incidence of talipes equinovarus foot deformity ([24](#)). In the first 6 months of life, spinal gibbus deformity may be noted by the parents ([11](#)) and often children have a history of frequent ear, nose and throat infections. A persistent nasal discharge is commonly present as well as conductive hearing loss due to middle ear effusions. The pediatric otolaryngologist has an important role in both early diagnosis and management of affected patients ([12](#)).

Between the ages of 6–12 months the facial features begin to change and are commonly described as “coarse,” being characterized by an increasing head circumference with frontal bossing, a wide nasal bridge and flattened mid face combined with an enlarged tongue. The skull becomes increasingly scaphiocephalic and by 18 months to 2 years the facial features are fully developed and the clinical condition becomes instantly recognizable to the majority of clinical geneticists and pediatricians ([Figures 102-10 and 102-11](#)).

In the first year of life, upper respiratory tract obstruction is often present and this can present with signs of obstructive sleep apnea which can be severe enough to precipitate right heart failure (25). The airway is generally narrowed, and there may be GAG deposition in the pharyngeal wall, tonsils, adenoids and soft tissues

around the larynx causing the glottis to narrow significantly during respiration. This can cause problems in some patients with anesthesia which should always be undertaken with great caution in MPS patients (26). The upper airway disease also contributes to Eustachian tube dysfunction which along with dysostosis of the ossicles and scarring from frequent episodes of otitis media contributes to the hearing loss that is very commonly found in these patients.

Other early features of MPS IH include umbilical and inguinal herniae, which may recur following surgical repair as well as enlargement of the liver and spleen. Development starts to slow down from the age of two years. The head circumference can enlarge rapidly as high-pressure communicating hydrocephalus may occur (Figure 102-12).

Growth also slows and affected patients develop contractures and joint stiffness. Corneal clouding starts to

**FIGURE 102-2** Hurler syndrome patient age 2 months.

**FIGURE 102-3** Hurler syndrome patient age 2 months.

**FIGURE 102-4** Hurler syndrome patient aged 2 months.

appear in the second year of life and becomes increasingly dense (Figure 102-13).

Cardiac disease is a significant complication and can present early with cardiac failure secondary to cardiomyopathy or later with valvular dysfunction (27,28). Progressive deposition of GAG in the myointima of the coronary arteries may be under recognized as a potential cause of cardiac complications, such as arrhythmia or ischemia (29,30).

DM progresses and affected children are short and most have a significant gibbus. Of more concern is that some patients have a hypoplastic or dysplastic odontoid and are unstable at the craniocervical junction. Flexion and extension X-rays should be performed on all patients with MPS IH to look for evidence of abnormal movement of C1 on C2 (Figure 102-14).

Throughout early childhood, the clinical picture continues to deteriorate and in the terminal stages of

the illness a combination of severe obstructive airway disease, neurological regression and cardiac involvement lead to death in most patients before the age of 10 years (23).

**102.2.1.1 Treatment of MPS IH.** For the past 30 years the standard treatment of choice for patients with MPS IH has been hematopoietic stem cell transplantation (HSCT), initially using bone marrow transplant (BMT) as the cell source but more recently and increasingly utilizing umbilical cord blood transplant (UCBT) or mobilized peripheral blood stem cells as the source. The initial publication by Hobbs et al. outlined the good short-term results of BMT with a reduction of urine GAG, resolution of hepatosplenomegaly and apparent arrest in developmental deterioration (31). It quickly became apparent, however, that even in the very best centers there was significant graft rejection, morbidity from graft versus host disease (GVHD) and mortality from various complications associated with the procedure (32,33). A number of complications that occur in MPS IH make transplantation more hazardous in this group of patients when compared with patients of a similar age undergoing transplantation for other

**FIGURE 102-5** Hurler patient age 2 months—under developed iliac bones (arrow).

genetic disorders, such as hemoglobinopathies. In particular, the presence of lower airway disease, a common complication in MPS IH, appears to be particularly significant (34). In terms of graft survival, better matching and busulfan targeting protect against rejection (35) and these measures plus the advances in pediatric intensive

**FIGURE 102-10** MPS IH facial features at diagnosis aged 8 months.

**FIGURE 102-11** MPS IH facial features at 27 months.

care, the increasing use of umbilical cord blood as a cell source and the use of enzyme replacement therapy (ERT) in the pretransplant period have all played a role in the improved graft and patient survival seen in the last decade (36–38).

**FIGURE 102-12** Communicating hydrocephalus MPS IH.

**FIGURE 102-13** MPS I corneal clouding MPS IH age 2 years 6 months.

Despite the use of ERT and improvements in graft survival and patient morbidity and mortality, the results of successful HSCT remain variable and there is often a considerable residual disease burden. It is usually impossible to predict the outcome of a successful transplant in an individual patient. Generally, the earlier the transplant performed, the higher the enzyme level achieved; and the more favorable the chimerism, the better the outcome (18), although there are exceptions to this (39).

In favorable cases, there is rapid resolution of hepatosplenomegaly, decline in urine GAG excretion and improvement in respiratory function including resolution

**FIGURE 102-14** MPS IH flexion X-ray of C spine with anterior slip of C1 on C2 (arrow).

of upper airways obstruction (40). In the heart, cardiomyopathy improves (41), coronary arteries are patent (42) but valve disease often progresses (43). The coarse hair and facial features soften and become more normal (Figures 102-15 to 102-17).

Corneal clouding clears, but not completely and most patients develop slowly progressive retinopathy with attenuation of the electroretinogram (ERG) (44). Sensorineural hearing loss does not improve post transplant and many children require amplification to prevent delay in language acquisition and speech and language therapy has an important role in trying to maximize the beneficial effects of transplantation on development (45). To complete the findings in the head and neck post transplant, complex dental abnormalities persist and require specialist input for management (46).

Untreated MPS IH is associated with rapid cognitive decline and HSCT can stabilize this but only if performed before significant cognitive impairment has occurred. Most transplanted patients continue to gain new skills but acquisition of these is often slower than normal and most patients whilst capable of being educated within a normal school do need extra help and some have significant special educational needs. Certainly, treatable factors that may impair developmental progress should be sought and managed. This would include sensory loss such as poor hearing or vision as well potentially more serious complications such as communicating hydrocephalus.

The long-term cognitive outcome following HSCT has been reported in a number of publications (33,47–52) and for a comprehensive review see Reference (53).

In addition, to the cognitive issues there is additional evidence to suggest that transplanted children have significant psychosocial impairment (54).

By far, the most disappointing result of transplantation is its failure to improve the DM which continues to progress, despite very good enzyme levels being achieved in many patients. Although odontoid dysplasia may improve post-HSCT (55), cervical instability, spinal deformity, hip dysplasia and genu valgum deformities all deteriorate, greatly impairing functional abilities and often requiring very invasive orthopedic procedures to try and improve skeletal outcome (56–61) (Figures 102-18 to 102-26).

Despite early orthopedic intervention, growth is often poor post-HSCT; and in addition, a number of endocrine abnormalities have been detected that may contribute to this. Growth hormone therapy may have a role in carefully selected patients (62,63). Some long-term female survivors remain fertile (64,65).

In addition to the major orthopedic complications, more minor problems such as carpal tunnel syndrome or trigger digits are also common and the hands are often short and stubby in post-transplant patients (66) (Figure 102-27).

It is unclear whether or not additional enzyme replacement therapy post-HSCT will lead to an improvement in

some of the residual disease burden (67). It is important that these patients are assessed, treated and followed up by multidisciplinary teams experienced in the management of MPS IH.

Enzyme replacement therapy alone has been used in patients with MPS IH (68). It was shown to be safe and associated with a reduction in urine GAG level and size of liver. Left ventricular hypertrophy decreased and sleep studies either showed improvement or stabilization in the majority of patients. As the drug cannot cross the blood–brain barrier, no improvement in developmental delay can be expected with ERT and therapeutic goals with ERT in this patient group should be limited to symptom control as part of a wider package of palliative care (69). Not all patients respond favorably to ERT as in some skeletal and visceral response is poor (70,71). Because the therapy is invasive, ERT should be prescribed for a limited period and only continued if measured, positive benefits can be seen. The details of enzyme replacement therapy are considered in more detail in the next section.

FIGURE 102-15 MPS IH BMT at age 10 years.

**FIGURE 102-17** MPS IH BMT at age 10 years.

### 102.2.2 Mucopolysaccharidosis IH/S (Hurler/Scheie Disease)

Patients with the attenuated forms of MPS I have an extremely heterogeneous disorder and there is considerable overlap between the types labeled as Hurler/Scheie or Scheie. Both have in common little or no cognitive involvement but the skeletal and visceral manifestations can vary widely from patient to patient. The differences cannot be distinguished by either enzyme deficiency or GAG excretion and mutation analysis is of limited value except when two nonsense mutations are found, as this is invariably associated with a severe phenotype (72).

In our own patients with Hurler/Scheie disease, mean age of onset of symptoms was 2.0 years (median 1.4 years; range 4 months–6 years) whilst the mean age of diagnosis was 6.5 years (median 4 years; range 1.3–32 years) indicating significant diagnostic delay in this group of patients a point of pivotal importance when considering the benefits of ERT (73).

The commonest clinical presentation in this group of patients is joint stiffness (40% of patients), often misdiagnosed as juvenile rheumatoid arthritis. Other features present at diagnosis in some patients include corneal clouding (13%), recurrent ear, nose and throat infections (27%), deafness (20%), umbilical hernia (27%), abnormal facial features (13%), hepatomegaly (13%) and short stature (13%) (73). Joint contractures in the absence of inflammatory changes have been flagged as an indication to test for attenuated forms of MPS disease (13,74).

With time the condition progresses and the facial appearance changes. The mandible is often very underdeveloped, limiting mouth opening and contributing the anesthetic difficulties seen in these patients (75–77) (Figures 102-28 and 102-29).

**FIGURE 102-18** MPS IH post-HSCT flexion and extension views of C spine demonstrating anterior atlantoaxial subluxation (arrow).

Corneal clouding worsens and is often associated with optic nerve swelling or a retinopathy (78,79).

Restrictive respiratory disease increases, cardiac valve lesions are common and may require surgery (80). The bone and joint disease limits mobility and dexterity with additional problems including an exaggerated lumbar lordosis with an underlying spondylolisthesis and also thickening of the dura in the cervical region causing compression on the spinal cord in this area, leading to cervical myelopathy (73). The surgical burden borne by the patients is significant (81) (Figures 102-30 to 102-32).

Some patients with MPS IH/S have significant cognitive impairment, but many are normal and most can cope with normal school with extra help for their physical and sensory disabilities.

Before enzyme replacement therapy became available, most patients with Hurler–Scheie disease died in their 20s

(mean 21.6 years, range 19.3–24.0 years, (23)) from the cardiorespiratory disease. It is too early to say whether or not this will be significantly prolonged by ERT.

### 102.2.3 Mucopolysaccharidosis IS (Scheie Disease)

The most attenuated form of MPS I is known as Scheie syndrome after the ophthalmologist who first described the condition in 1962 (82). Most patients are diagnosed as teenagers (mean age of diagnosis 13.3 years, median 7 years, range 2.5–40 years (73)). Patients often have considerable symptoms in childhood and most by the age of 12 years have a combination of, hepatomegaly, joint contractures, cardiac valve abnormalities and corneal clouding (83). Later complications include carpal tunnel syndrome (84) and cervical myelopathy secondary to

**FIGURE 102-19** T1 and T2 weighted images of the C spine (same patient as Figure 102-20).

**FIGURE 102-20** X-ray of C spine with bone graft in situ. Patient wearing halo fixation device.

dural thickening (85). Cognitive impairment is not usually a feature of Scheie disease and prolonged survival is usual although considerable disability may be present and most patients have undergone a significant number of surgical procedures (81).

**102.2.3.1 Treatment of MPS IH/S and MPS IS.** ERT using recombinant human  $\alpha$ -L-iduronidase, laronidase, (Aldurazyme, BioMarin Pharmaceutical Inc., Novato, California and Genzyme Corp., Cambridge, MA) is now part of the standard therapy for MPS IH/S and MPS IS. In a double-blind, placebo-controlled clinical trial in 45 patients with attenuated MPS I, laronidase was shown to reduce urine GAG excretion and to improve respiratory function and physical endurance (86). Laronidase is a life-long therapy and is given by weekly intravenous infusion over 3 to 4 hours. It has generally proven to be safe even when given to severely affected patients that one would expect to have null mutations (68).

A limited number of prolonged follow-up studies of MPS I patients treated with laronidase suggest that improvements are maintained in many areas (87,88), but like the results of HSCT this can be variable. Assuming no problems with the initial infusions,

the treatment can be administered in the patient's home (89).

The biochemical effect of ERT is possibly less than that achieved by HSCT (90) but it is difficult to directly compare the two populations of patients treated by these different modalities and both have been demonstrated to restore dermal fibroblast morphology (91).

It has been clearly demonstrated both in the MPS I dog and MPS I human that early treatment gives the best chance of a successful outcome with treatment (92,93).

The limited reports of the results of long-term ERT in MPS IH/S and MPS IS suggest that over a 6-year period respiratory function tests remained stable and there is a small increase in distance walked in a 6 min walk test (88). Joint mobility may improve but this may take place gradually over a prolonged period of time (94,95). Dural thickening is not improved by intravenous ERT, but intrathecal ERT may be effective in this situation in carefully selected patients (96). Cardiac valve lesions do not improve with ERT and the majority of patients with significant corneal or optic disc changes continue to deteriorate.

The vast majority of patients develop antibodies to laronidase (93%, (88)). The significance of these remains uncertain but in the animal model, at least, the induction of immune tolerance has a significant impact on the efficacy of therapy and may have some relevance to the human situation (97). About half of all patients treated will have an infusion associated reaction (53%, (88)), but fortunately the majority of these will be mild and very easily managed with premedication with an antihistamine or slowing down the rate of infusion (98). In most patients, the frequency and intensity of reactions decreases over time. Anaphylactic reactions have been reported in the product safety information ([http://www.aldurazyme.com/hc/abt/az\\_us\\_hc\\_safety.asp](http://www.aldurazyme.com/hc/abt/az_us_hc_safety.asp)) but in practice these must be very rare.

### 102.3 MUCOPOLYSACCHARIDOSIS II (HUNTER SYNDROME)

MPS II (Hunter syndrome) is an X-linked recessive disease caused by the deficiency of the lysosomal enzyme iduronate-2-sulfatase (I2S). I2S functions to cleave O-linked sulfate moieties from both DS and HS; therefore, due to the deficiency of I2S, these molecules progressively accumulate in MPS II. Apart from in the Far East, MPS II is not as prevalent as MPS I, and occurs an estimated incidence of one in 162,000 live births (99). Like MPS I, the clinical phenotype is secondary to GAG accumulation in almost all cell types, tissues and organs of the body. Although the condition is X-linked, a number of affected females have been reported. Most have a severe clinical phenotype and preferential X chromosome inactivation of the nonmutant allele resulting in low I2S enzyme activity (100). Affected female patients should be managed in the same way as affected males.

**FIGURE 102-21** MPS I post-HSCT pre- and post-op kyphosis surgery.

**FIGURE 102-22** MPS I post-HSCT pre- and post-op kyphosis surgery.

**FIGURE 102-23** MPS I post-HSCT pre- and post-op kyphosis surgery.

**FIGURE 102-24** Genu valgum deformity post-HSCT.

MPS II is a very heterogeneous disorder, both in terms of age at onset of symptoms and disease severity. The approach to recognition and diagnosis has been reviewed recently (101) and will be summarized here.

The median age of onset of symptoms and diagnosis of Hunter syndrome is 1.5 and 3.5 years, respectively (102). Many patients have already undergone surgical intervention before diagnosis and repeated early surgical interventions especially for hernias are common. Such a surgical history should raise suspicion of the possibility of an underlying MPS disorder (103). Most affected male patients are normal at birth but during the first 3 years of life grow rapidly and are often large infants. Growth velocity usually slows by the end of the third year and ultimately most patients are small (104).

It is usual to divide the patients into two groups, “severe” or “mild” based on survival and the presence or absence of neurodegeneration and cognitive impairment. This is an oversimplification as the disease, like MPS I, is a spectrum and it is often difficult at presentation to

predict neurological outcome. Retrospective studies of patients with MPS II have shown that patients with neurological involvement have an earlier age of onset of symptoms (2.47 years) compared with those with no cognitive impairment (4.3 years) and in addition have a much lower mean age at death (11.7 years in severe patients and 21.7 years in mild or attenuated patients (105)). There is some evidence that brain imaging may help to determine at an early stage patients that are destined to be significantly cognitively impaired but many more patients need to be studied to confirm this (106,107).

The most common presentation is a history of recurrent upper airway infections combined with a coarsening of the facial features with an enlarged head circumference. There is flattening of the nasal bridge and prominent supraorbital ridges and X-ray examination reveals evidence of DM (101) (Figure 102-33).

When compared with MPS IH at a similar age, it is clear that patients with MPS II have less severe skeletal involvement at a young age and are generally less

**FIGURE 102-25** Genu valgum corrected by medial epiphyseal fusion using eight plates.

**FIGURE 102-26** X-ray and MRI of hips in 5-year-old MPS IH patient post BMT. Shallow acetabula shown on MRI to be due to failure of ossification of lateral border of the acetabulum. Coxa valga also present (arrow).

dysmorphic, explaining the difference in mean ages at diagnosis (9 months MPS IH compared with over 2 years for patients with MPS II). [Figure 102-34](#) illustrates this point.

Organ involvement is broadly the same as in MPS I. Frequent upper respiratory tract infections, mixed conductive

and sensory hearing loss ([108](#)) and obstructive sleep apnea are common ([109](#)).

Progressive airway obstruction is common and is combined with restriction due to the immobility of the thoracic cage secondary to skeletal involvement. Tracheobronchomalacia is common and the end result may

**FIGURE 102-27** 13-year-old MPAS IH patient post-HSCT. Short stubby hands.

be progressive respiratory failure and noninvasive ventilation is often required at night to maintain airway patency (110,111). Video 102-1 is a video of a laryngoscopy on a teenage boy with MPS II. Abundant soft tissue around the larynx is seen to prolapse into the orifice to cause obstruction during inspiration. Later in the video, the trachea is seen as narrowed and partially collapsed due to tracheomalacia.

In older patients, tracheal stenosis may be an additional problem (112).

The ocular findings in MPS II differ from those seen in MPS I. Corneal clouding is not a feature and raised intraocular pressure is very rare. The sclera is usually thicker than normal (113) and optic disc edema can mimic papilledema (114). Figure 102-35 shows the disc appearance of a teenager with MPS II. Despite this appearance, visual acuity was normal. Progressive retinopathy associated with attenuation of the ERG and thinning of the retina can lead to progressive visual loss (115).

Another finding that seems to be specific to MPS II is a distinctive papular skin lesion found around the scapulae and upper thighs of affected boys (Figure 102-36). The papules are ivory colored and range in size from 0.2 to 0.5 cm in diameter and often coalesce as seen in Figure 102-37. Biopsy of the lesions reveals interstitial mucin deposited throughout the reticular dermis (116).

Almost all affected boys develop cardiac valve lesions and cardiac disease is a common cause of death in this cohort (117).

Central nervous system involvement is variable. In severely affected patients it manifests with delay in development, behavioral disturbance and then progressive loss of skills between the ages of 5 and 10 years. Epileptic seizures are common and death usually occurs in the first or second decade of life. At the other end of the

clinical spectrum, patients with attenuated disease may have normal or near-normal cognitive abilities despite significant somatic disease.

Despite normal cognition, magnetic resonance imaging (MRI) scans of the brain in attenuated patients are often very abnormal (118). Cervical myelopathy due to hyperplasia of the transverse ligament and dural thickening is a common complication from teenage years onwards. This usually presents with a gradual loss of endurance coupled with difficulty with rising from a chair. If untreated, it progresses to a slowly ascending paralysis with sphincter involvement. Prompt cervical decompression can prevent this progression (Figure 102-38).

Carpal tunnel syndrome is common in affected males but is often asymptomatic. It should be screened for from a young age and surgical decompression formed early to preserve nerve function (119).

### 102.3.1 Treatment of MPS II

Multidisciplinary management is essential for affected patients with MPS II. Patients require access to ENT surgery, pulmonologists, orthopedists, neurosurgeons, cardiologists, ophthalmologists and audiologists among others. Skilled anesthesiology is a prerequisite for any planned or emergency surgical procedure. In severe neurologically impaired patients, management may be similar to that described for patients with MPS III and may include anticonvulsants, gastrostomy feeding and behavior modifying medications.

HSCT has not been reported as being successful in preventing the neurological deterioration that occurs in severe MPS II and is therefore not routinely offered as a form of therapy for these patients (120,121). It should be noted however that the numbers treated are small and the

patients have been offered treatment at a relatively late stage in their illness in the majority of cases. No systematic clinical trials of HSCT in MPS II have been performed and so these results should be interpreted with some caution.

Idursulfase (Elaprase, Shire Human Genetic Therapies Inc., Cambridge, MA, USA) is a recombinant form of I2S produced in a continuous human cell line and is used as ERT in MPS II. A large clinical trial demonstrated clinical benefit from weekly Idursulfase in a dosage of 0.5 mg/kg/week by intravenous infusion. Ninety-six patients were studied and the primary efficacy end point used was a composite of distance walked in 6 min and

the percentage of predicted forced vital capacity based on the sum of the ranks of change from baseline (122). There have been very few follow-up studies reported but the drug has been evaluated in children below the age of 5 years (123) and in adults with attenuated disease (124). A positive effect on growth has been reported especially in patients treated from under the age of 10 years (125). Although a number of patients have had infusion associated reactions (98) and some develop antibodies to idursulfase, the treatment is generally safe and can be administered in the patient's home (126).

Like laronidase, elaprase is unable to cross the blood-brain barrier and therefore, intravenous therapy cannot prevent or correct the neurological deficits seen in severe MPS II. A clinical trial of intrathecal ERT has commenced in these patients: (<http://www.clinicaltrials.gov/ct2/show/NCT00920647?term=mucopolysaccharidosis+type+II&rank=7>).

#### 102.4 MUCOPOLYSACCHARIDOSIS IIIA (SANFILIPPO SYNDROME, MPS IIIA)

MPS III is the most common of the MPS disorders with an estimated incidence of all types together of around

FIGURE 102-28 Teenager with MPS IIH/S—note micrognathia.

FIGURE 102-29 Teenager with MPS IIH/S—note micrognathia.

1:60,000–70,000 births (99). All of the disorders result from a failure to catabolize the GAG heparan sulfate. The enzyme deficiencies behind each of the subtypes of MPS III are documented in Table 102-1. MPS IIIA, the commonest of the MPS III subtypes in Western Europe is associated with a deficiency of the enzyme heparan-N-sulfatase (HNS). In our own patients, MPS IIIA was the clinical subtype in 47 out of the first 62 patients seen and assessed in our own unit (127).

MPS IIIA, like all of the MPS conditions, is a heterogeneous disorder. In our patients, the mean age at diagnosis was 4.9 years (range 0.8–16 years) and this seems consistent with other, more recent, studies (128,129).

Although diagnosis is usually made after the age of 4 years, the patients often have symptoms from the first year of life. Speech delay, recurrent ear, nose and throat infections, diarrhea and hearing loss are common presenting features. The absence of significant somatic disease usually means that a diagnosis of MPS is not

considered by the nonspecialist pediatrician as a potential cause for what are very nonspecific clinical symptoms. Enlargement of the liver and spleen and cardiac lesions are rare and the facial features are much “softer” than MPS I or II (Figure 102-39).

In a typical patient, the phenotype evolves over three overlapping phases (127). The first phase (usually before diagnosis) consists of developmental delay alone. This is most often delay in speech development and initially this is often ascribed to coexisting middle ear disease but when grommets are inserted there is no improvement in speech acquisition. In addition, many patients have

**FIGURE 102-30** Fixed flexion deformities of the fingers in a patient with MPS IH/S.

**FIGURE 102-31** MPS IH/S spondylolysis (arrow).

**FIGURE 102-32** (A) MRI scan of cranial–cervical junction clear rim of cerebrospinal fluid seen around the upper cord. (B) MRI scan CCJ of MPS IH/S patient with dural thickening (no rim of CSF) and early signal change in cord (arrow).

**FIGURE 102-33** MPS II facial features age 8 years.

**MPS II**

**MPS I**

**FIGURE 102-34** Two 4-year-old children with MPS II and I.

gastrointestinal problems with chronic diarrhea being particularly prevalent (130).

The second phase of the illness usually begins around the age of 3 or 4 years and is characterized by severe behavioral disturbance. The behavior is challenging and characterized by increasingly frequent and severe temper tantrums. Hyperactivity is usual and is often combined with a severe sleep disturbance. There may be panic attacks and as the children are normally grown they can be very difficult to manage in social situations.

At the end of the first decade, the illness changes again as children enter the third and final stage of the illness. The patients become quieter, fall more frequently and develop neurological dysphagia. Gastrostomy feeds become necessary, the children become wheelchair bound and a significant number of patients develop seizures.

The radiological changes of DM are generally mild but patients are prone to vascular necrosis of the femoral head which may be unilateral or bilateral (127) (Figure 102-40).

**FIGURE 102-35** MPS II full optic discs both eyes.

**FIGURE 102-36** MPS II papular rash around scapula.

**FIGURE 102-37** MPS II patient with normal cognitive development.

In typical, severely affected patients, death usually occurs in the second or early in third decade of life. The usual cause of death is respiratory infection in a profoundly handicapped child or young adult.

In keeping with other CNS disorders, precocious puberty has been reported in MPS III (131). Like all the MPS disorders, there are attenuated patients and a late onset visceral presentation without neurological disease has been reported in MPS IIIA (132).

Numerous mutations have been identified in the *HNS* gene and in western Europe the missense mutation p.R245H is prevalent (35% of alleles in Germany, 57% of alleles in The Netherlands) (133). Establishing a good genotype–phenotype correlation in MPS IIIA is complicated by the presence of a number of polymorphisms of

**FIGURE 102-38** MPS II normal MRI scan—clear rim of CSF around cord in C region MPS II with cervical myelopathy no CSF visible around cord in C region (arrow).

**FIGURE 102-39** MPS III facial features.

unknown significance but can be done (129). One mutation (p.Ser298Pro) is associated with a slowly progressive phenotype and survival well into adult life (134). These patients can be very difficult to diagnose as the very slow progression can be missed and the condition misdiagnosed as a static encephalopathy.

### 102.5 MUCOPOLYSACCHARIDOSIS IIIB (SANFILIPPO SYNDROME, MPS IIIB)

MPS IIIB is caused by a deficiency of the enzyme *N*-acetyl- $\alpha$ -D-glucosaminidase (NAGLU) which, like a deficiency of HNS, leads to an accumulation of HS and a Sanfilippo

**FIGURE 102-40** MPS III unilateral hip dysplasia.

phenotype. In the United Kingdom, the clinical phenotype and disease progression is exactly the same as that described for MPS IIIA, but the disease is less prevalent (127). In The Netherlands, however, MPS IIIB presents, predominantly, as an indolent, slowly progressive disorder compatible with prolonged survival and a median age at death of 43.5 years (135,136).

### 102.6 MUCOPOLYSACCHARIDOSIS IIIC (SANFILIPPO SYNDROME, MPS IIIC)

The gene responsible for MPS IIIC, *TMEM76* (the transmembrane protein 76 gene), is the most recently identified MPS gene (137) and it encodes for an enzyme (acetyl-coenzyme A: $\alpha$ -glucosaminide *N*-acetyltransferase, HGSNAT) that is active in the lysosomal membrane. HGSNAT catalyzes acetylation of the terminal glucosamine residues of the GAG heparan sulfate prior to its hydrolysis by  $\alpha$ -N-acetyl glucosaminidase (138).

A deficiency in HGSNAT leads to accumulation of heparan sulfate and a Sanfilippo phenotype. Most of the missense mutations identified affect folding of the mutant protein raising the possibility of pharmaceutical chaperones as a potential therapy in the future (139). MPS IIIC is a rare disease with an estimated prevalence of 0.07 per 100,000 live births (99) and generally results in an attenuated MPS III phenotype. In a study of 29 patients from The Netherlands, the mean age of death was 34 years (range 25–48 years) (140).

## 102.7 MUCOPOLYSACCHARIDOSIS IIID (SANFILIPPO SYNDROME, MPS IIID)

MPS IIID is caused by a deficiency of the lysosomal hydrolase  $\alpha$ -N-acetylglucosamine-6-sulfate sulfatase (GNS). GNS cleaves the sulfate at the 6-hydroxyl position moiety of N-acetylglucosamine from heparan sulfate leading to accumulation of this metabolite and a Sanfilippo phenotype (141).

The disorder is very rare (1:1,000,000 live births) (99) and the largest case series in the literature describe 12 patients (142). The patients reported have clinical features characteristic of MPS III A, B and C and no significant differences between the phenotypes is apparent.

### 102.7.1 Treatment of MPS III

The treatment of MPS III is symptomatic and palliative. The condition does not respond to HSCT (143) and ERT has not yet been developed.

Sleep disturbance can have a profound effect on the health of carers and needs to be tackled aggressively. Melatonin has the highest chance of success but in some patients sleep disturbance remains resistant to all forms of therapy (144). A clear disturbance of circadian rhythm has been demonstrated in the mouse model of MPS III and presumably similar defects in the human contribute to the sleep disturbance (145).

The challenging behavior during the day can also be difficult to manage. The hyperactivity responds poorly to behavior therapy and psychostimulants such as methylphenidate. Usually, major tranquilizers are needed and the only one that has been examined in a randomized trial in MPS III patients is risperidone (0.125–2 mg/d) (146). In this study, most improvement was seen in hyperactivity and defiance with less effect noted on conduct disorder. In the mothers of the treated children, there was a significant reduction in anxiety and depression scores. In this study, risperidone appeared to be both effective and safe but in other patients extrapyramidal side effects have been reported, especially in patients on relatively high dose (>4 mg/d) (147).

Toward the end of the first decade of life, neurological dysphagia becomes problematical for a significant number of patients. Weight loss, increasing time taken to feed and chest infection herald the need for gastrostomy

placement to prevent aspiration. Inhibition of saliva production can be successfully achieved by either scopolamine patches or glycopyrrolate. Both have been subjected to controlled trials in disabled patients and found to be effective but both have a significant incidence of side effects, in particular, agitation (148,149).

Over the age of 8 years, seizures become more common. These can be a mixture of different types and no specific anticonvulsant is better than another in management. Other nonepileptic paroxysmal behaviors also occur particularly at night. The etiology of these is often unclear but parents often ascribe them to pain as during the episode the patients often seem very distressed. Management of these episodes can be very difficult and one usually has to rely on sedatives running the risk of over sedation in particularly difficult patients. Video 102-10 is a short clip of a 15-year-old MPS III girl demonstrating the characteristic “distressed” behavior often seen in MPS III.

More experimental forms of therapy are in development. As this is a primary CNS disorder, a more inventive method of therapy will be required as intravenous ERT cannot be effective in such disorders as the enzymes are unable to cross the blood–brain barrier. Three approaches are in development and potentially more could be applicable in the future:

- (1) Intrathecal enzyme replacement therapy is in human clinical trial (December 2010) for MPS IIIA (<http://clinicaltrials.gov/ct2/show/NCT01155778?term=mucopolysaccharidosis+type+III&rank=1>)

Studies in both mice and dogs suggest that this approach may reduce primary substrate storage (150,151). In MPS IIIA mice, ERT from birth (when the blood–brain barrier is still open) delays the onset of neurological and behavioral disturbance seen in the untreated animal (152). Clearly, there are a number of additional safety issues to be considered with this therapy in humans. The nature of the delivery device, the necessary frequency of infusion and the possibility of infection or immunological problems are just a few of the variables that need to be carefully considered with this method of therapy.

- (2) Genistein, a naturally occurring isoflavone, has been proposed as a potential treatment for MPS III (and other MPS disorders) as it can inhibit the synthesis of GAGs (153). This approach to therapy is known as substrate reduction therapy (SRT) and is an alternative approach to enzyme enhancement (by ERT, HSCT or gene transfer). To be successful, there must be a small amount of residual enzyme activity to catabolize substrate already stored whilst the SRT drug hopefully prevents accumulation of further substrate thus restoring metabolic balance.

Genistein is known to occur in many different health food supplements, but not all contain sufficient amounts to inhibit GAG synthesis in vitro (154). In mouse models

of MPS III, the best results are obtained with high dosages of chemically synthesized, pure genistein aglycone (155,156). A placebo-controlled study is required to assess the potential of genistein therapy in humans.

Rhodamine B, another inhibitor of GAG synthesis has also been used in murine MPS IIIA with promising results but has not yet been tried in humans (157).

(3) Gene transfer using a variety of vectors has been attempted and successfully completed in murine models of both MPS IIIA and IIIB (158,159). In affected MPS IIIB dogs, immunosuppression is necessary to prevent elimination of transduced cells by neuroinflammation, but subsequent results suggest that this approach may be applicable for use in affected humans (160).

### 102.8 MUCOPOLYSACCHARIDOSIS IVA AND IVB (MORQUIO SYNDROME, MPS IVA, MPS IVB)

MPS IVA is very different from the other MPS disorders. A deficiency of *N*-acetylgalactosamine-6-sulfatase (GALNS) leads to a failure to degrade and therefore an accumulation of KS and C6S resulting in a severe skeletal dysplasia (161). MPS IVB is a rarer, distinct and different genetic disorder caused by a deficiency of the enzyme  $\beta$ -galactosidase due to defects in the  $\beta$ -galactosidase gene (*GLB1*) (162). The major substrates for  $\beta$ -galactosidase are KS, galactose-containing oligosaccharides as well as GM1 ganglioside, GA1, and lactosylceramides. The primary disorder associated with defects in the *GLB1* gene is GM1 gangliosidosis. The mutations in *GLB1* that underlie Morquio type B cause the enzyme to lose specificity for KS but retain the ability to degrade GM1 ganglioside. Several missense mutations in *GLB1* have been identified as causing Morquio type B but not all mutations in *GLB1* are predictive of phenotype (163). From a

clinical point of view, the skeletal dysplasia in Morquio B disease is generally milder than that seen in classical MPS IVA and the patients usually attain greater height. The condition is usually distinguished from juvenile GM1 gangliosidosis by the absence of cognitive impairment but there can be significant overlap. The approach to management follows that of patients with MPS IVA.

MPS IVA is rare with a reported prevalence of approximately 1:200,000 live births (99). Like the other MPS disorders, it is heterogeneous but the most common presentation is with a very severe skeletal dysplasia associated with profound growth failure (final adult height 95–110 cm). Numerous mutations and polymorphisms have been identified in the *GALNS* gene in MPS IVA but there is only limited genotype:phenotype correlation (164). There is surprisingly little reported on the histological changes in bone and connective tissues in affected patients. The cartilage cells in the epiphyseal plate are disorganized and vacuolated and there is loss of the normal columnar architecture. Calcification in the plate is reduced (165). The extracellular matrix of cartilage is also disorganized resulting in a cartilage more prone to early degeneration (166). The end result is growth failure and a tendency to early onset arthritic changes in affected joints.

There have been recent reviews of the clinical manifestations and disease course in MPS IVA and in addition growth charts for affected patients have been produced (167,168). In our own patients, predominantly affected by severe MPS IVA, the diagnosis is usually made clinically toward the end of the first year of life (169). The parents of affected children most often notice a lower thoracic-upper lumbar vertebral gibbus or a pectus carinatum deformity of the chest (Figure 102-41).

The radiological abnormalities are distinct from the DM seen in other MPS disorders. In MPS IV there is platyspondyly and the odontoid is always dysplastic (170). In severely affected patients the odontoid is

MPS IV patient at age 3 years

FIGURE 102-41 MPS IV patient at age 3 years.

**FIGURE 102-42** MPS IV hypoplastic odontoid and anterior subluxation of C1 (arrow).

**FIGURE 102-43** Same patient as Figure 102-42 MRI scan showing compression at craniocervical junction with signal change within the cord (arrow).

virtually absent and instability at the craniocervical junction is a major cause of morbidity and potential mortality. In addition, the hips are dysplastic and there is genu valgum deformity at the knees (Figures 102-42 to 102-44).

Although MPS IVA is a multisystem disease most time is spent analyzing the patient's craniocervical junction and assessing the presence or absence of instability and the potential risk of cervical cord damage (cervical myelopathy). MRI combined with plain radiology flexion and extension studies are a requirement for every patient with MPS IV. Figure 102-45 shows a typical MRI appearance of the C spine of a young MPS IV patient in whom plain radiology suggested instability at the craniocervical junction. The MRI scan shows an anterior soft tissue mass indenting the cord and causing compression in addition to the instability. Histological examination of this tissue shows that it has the appearance of nonspecific immature fibrous and fibrocartilaginous tissue (171).

The clinical presentation of cervical myelopathy can be acute with sudden death due to upper cord/brain stem

**FIGURE 102-44** Lateral spine—platyspondyly and gibbus. Lower limbs dysplastic hips and genu valgum deformity.

contusion (2 out of 37 patients in our original series (169)), but is more commonly insidious with loss of exercise tolerance often the first sign. If left untreated, there is ascending paralysis with initially hyper reflexia and clonus in the lower limbs followed by weakness and hyper reflexia in the upper limbs.

Other skeletal involvement includes hip dysplasia and genu valgum and both of these abnormalities can limit mobility and as a consequence many teenagers and young adults with MPS IVA prefer to use powered wheelchairs rather than relying on their own motor skills.

Delayed ossification of the carpal bones and ligamentous laxity at the wrists leads to very poor hand function. Grip is often very weak causing difficulties with dressing, personal hygiene and writing.

Aches and pains in various joints plus the onset of arthritic changes early in life compound the misery and difficulties caused by the skeletal dysplasia.

Outside of the skeleton, the major effects of the disease are on hearing, breathing, vision and cardiac function. Hearing impairment due to a combination of conductive and sensorineural deafness is common. Upper airway obstruction due to tonsillar and adenoidal hypertrophy is exacerbated by tracheomalacia and by the tendency of the trachea of affected patients to “kink” when the neck is flexed. Many children and young adults hold their necks in an extended posture to keep their airway open. Figure 102-46 illustrates the tracheal abnormalities in a young teenager with MPS IVA. The trachea is “kinked,” tortuous and narrower than normal.

As the disease progresses, a restrictive respiratory defect becomes more obvious and whilst formal respiratory function tests are difficult to interpret due to the short size of the patients it is clear that the thoracic organs are severely compressed by the small bony thorax and respiratory failure is a common cause of death in early adult life in severely affected MPS IVA patients.

**FIGURE 102-45** MPS IVA C spine MRI (T1 and T2 images) anterior soft tissue compression at tip of dysplastic odontoid process (arrow).

**FIGURE 102-46** MPS IVA CT reconstruction of trachea.

In the heart, early onset coronary artery disease has been reported in MPS IV but in practice this is not common (172). Valve abnormalities are much more prevalent primarily affecting the left side of the heart (173). The most common ophthalmological abnormality is fine corneal stromal clouding this is rarely severe enough to require any specific therapy. Both glaucoma and retinopathy have been reported in isolated cases but neither has been seen in our patient group. Dental abnormalities are universal in severely affected patients (174). Pointed cusps, thin enamel, spade shaped incisors and pitting are common and the patients are prone to extensive dental carries unless very careful dental follow-up is carried out.

Attenuated patients have a very different presentation. Common mutations causing a mild phenotype have been reported in both Finnish (175) and Northern Irish (176) patients. Typically affected patients are taller but are prone to premature osteoarthritis. Bilateral hip

and knee replacement surgery is commonly required to maintain pain-free mobility. Figure 102-47 illustrates a typical young teenager with attenuated MPS IVA (photographs courtesy of Dr Fiona Stewart, Consultant Clinical Geneticist, Belfast, Northern Ireland).

### 102.8.1 Treatment of MPS IVA

A clinical trial of ERT in MPS IV has commenced (December 2010, <http://clinicaltrials.gov/ct2/show/NCT00884949?term=mucopolysaccharidosis+type+IV&rank=3>). An improvement in growth and respiratory function in affected patients treated by ERT will be a prerequisite for a successful study. Preclinical studies in a murine model of MPS IVA have demonstrated clearance of KS from the blood and tissues of affected animals. Unfortunately, affected mice have very little skeletal disease and so these results are difficult to extrapolate to the human situation (177).

Surgical treatment remains a very important part of management. The timing of intervention of cervical decompression and fusion is of critical importance. The risks of anesthesia must be weighed up carefully against the risk of leaving a potentially unstable patient untreated. A prophylactic approach to surgery has long been advocated (178) and there have been few recent advances to alter this general advice. It has been our practice to perform posterior cervical decompression with occipitocervical fusion using a skull graft as the strut as illustrated in Figure 102-50. Immobility is maintained in the postoperative period by use of a halo vest fixation device for 34 months (Figures 102-22 and 102-48).

Complications of the halo vest include pin site infection and loosening, but these are usually easily managed. Long term, some patients develop further abnormal movement in the spine below the fused segment and the occasional patient will require repeat surgery. In our experience failure to fuse is rare. As with all operations on or near to the spinal cord there is a risk of damage to

the cord at surgery, either directly or by interfering with the blood supply to a segment of cord.

Lower limb and pelvic surgery is also often performed in affected patients in an attempt to maintain mobility and to prevent later osteoarthritic changes. There is no consensus as to what surgery should be performed and at what age. Surgery to correct genu valgum is often undertaken. Temporary hemiepiphysiodesis cannot be successful in severe MPS IVA as the patient's growth velocity is minimal from the age of 3 years onwards and in most MPS IVA patients satisfactory leg alignment can only be achieved by wedge osteotomy.

Other more invasive surgical treatments include both hip and knee replacements (179,180). The main indication for replacement surgery would be to effectively manage pain from the joint deformity and arthritic changes that are commonly present in the abnormal joints.

Like other MPS disorders ear, nose and throat surgery including grommets, tonsillectomy and adenoidectomy are commonly performed. In contrast to some other MPS disorders, heart valve surgery (181) and corneal transplant are rarely required (182).

Management of the respiratory disease is particularly challenging. The etiology is multifactorial with obstruction (in some cases positional, (183)), restriction due to thoracic deformity (184) and malacic changes in the trachea and bronchi (185). Patients commonly present with hypoxemia during sleep but eventually they become breathless and increasingly distressed during the day whilst awake. The lack of any significant respiratory reserve makes any superadded respiratory infection potentially life threatening. Gradually, hypercapnia supervenes and noninvasive ventilation is often suggested at this stage and whilst this can keep

FIGURE 102-47 Attenuated MPS IVA age 12 years.

FIGURE 102-48 MPS IV post-decompression and fusion.

a malacic airway patent during sleep, it is less effective in treating the restrictive element of the respiratory disease. Most families, in our experience, have opted out of tracheotomy and invasive ventilation as they perceive the quality of life that this allows to be very poor and at this stage a palliative care program would be instituted.

### 102.9 MUCOPOLYSACCHARIDOSIS V (SCHEIE SYNDROME, MPS V)

Before being recognized as an  $\alpha$ -iduronidase defect, Scheie disease was classified as MPS V. The entry is retained for historical purposes only.

### 102.10 MUCOPOLYSACCHARIDOSIS VI (MAROTEAUX-LAMY SYNDROME, MPS VI)

MPS VI is caused by a deficiency of lysosomal enzyme N-acetylgalactosamine-4-sulfatase secondary to defects in the aryl sulfatase B (*ARSB*) gene which is located on chromosome 5 (5q13–5q14 (186)). The enzyme deficiency results in the accumulation of partially degraded DS which appears to be responsible for the disease manifestations. Another GAG, C4S is also broken down by the same enzyme but accumulation of this substrate and its derivative products does not appear to cause intracellular problems.

MPS VI is a rare MPS disorder with a reported prevalence of approximately 1:250,000 live births (99). Like other MPS disorders, it is heterogeneous. Unlike other MPS disorders that are usually divided into severe and attenuated phenotypes, the spectrum presented by MPS VI is usually divided into “rapidly progressing” disease or “slowly progressing” disease, correlating with the severe and mild ends of the clinical spectrum, respectively.

Patients with forms of the disease between these two extremes are also seen.

A cross-sectional natural history study of 121 MPS VI patients has provided insights into the relationship between disease severity, rapidity of progression and urine GAG excretion (187). In this study, high urinary GAG values (>200 mg/mg creatinine) were associated with rapidly progressive disease, impaired endurance, poor respiratory function, greater joint restriction and short stature. An attempt to correlate disease severity with *ARSB* mutation identified a clear correlation between genotype and urinary GAG and confirmed that urinary GAG values could be used to predict likely disease severity, confirming the findings of the natural history study (188).

In patients with rapidly progressing MPS VI, the onset of symptoms is usually before the age of 3 years and a number of patients are diagnosed in the first year (189,190). Affected patients have a phenotype rather like MPS IH with the exception that cognitive impairment is not present. The DM is severe and growth consequently severely restricted. In rapidly progressing patients, it is unusual for the patients to achieve a final adult height of greater than 120 cm (187). Most other organ systems are affected. The facial features are characteristic and again similar to MPS IH. The mid face is underdeveloped, the gums are thick and the tongue is large and protruding. Dental eruption is often considerably delayed (191). Hernias are common and the parents may notice a spinal deformity (Figure 102-49).

Upper airway obstruction and a persistent nasal discharge are universal. Many patients have obstructive sleep apnea and most require ear, nose and throat surgery (192). A combination of conductive and sensorineural hearing loss is usual. Anesthesia is hazardous and must only be performed by anesthetists experienced with the disorder.

**FIGURE 102-49** MPS VI patient aged 10 months. Parents were concerned about pectus deformity of chest. X-rays suggested an MPS disorder (Figure 102-53).

**FIGURE 102-50** Same patient as Figure 102-42 hypoplastic, beaked lumbar vertebrae (arrow).

The eye can be severely affected in MPS VI and visual impairment is unfortunately not uncommon. The orbit is shallow and as a result proptosis is common. Corneal clouding can be severe and raised intraocular pressure can occur. Retinopathy is rare but the optic nerve is vulnerable to both raised intracranial pressure as well as thickening of the dura and sclera. Sudden loss of vision can occur and the patients require careful ophthalmological follow-up (193) (Figure 102-51).

Lower respiratory tract involvement becomes progressively worse over time. Restrictive respiratory disease and airway obstruction are a significant cause of morbidity and mortality in rapidly progressing patients from the age of approximately 10 years onwards. Pulmonary hypertension secondary to chronic hypoxemia can occur and a number of patients will require noninvasive ventilation and some tracheostomy to maintain oxygen levels (192).

Cardiac disease ranges from cardiomyopathy in early infancy to chronic and progressive valve lesions. Valve replacement may be necessary but is technically challenging in rapidly progressing patients (194–196).

Orthopedic issues include spinal deformity with kyphosis and scoliosis, large joint contractures, claw-hand deformity, carpal tunnel syndrome and finally spinal cord compression secondary to dural hyperplasia. Studies in animal models have shown that accumulation of the GAG DS can have a profound effect on articular chondrocytes with a high rate of apoptosis and the release of inflammatory cytokines into the joint space (197). A combination of structural abnormality or deformity plus inflammation appears to be central to the development of the severe skeletal dysplasia seen

**FIGURE 102-51** Rapidly progressing MPS VI patient age 10 years. Proptosis, corneal clouding, large tongue.

in patients with rapidly progressing disease. This can be seen clearly in the pelvis and hip-joint X-rays where dysplastic acetabulae are associated with fragmented flattened and fragmented femoral heads as illustrated in Figures 102-52 and 102-54.

As well as kyphosis, scoliosis may occur and this can require major spinal surgery to correct (Figure 102-53).

Virtually, all patients with rapidly progressing disease will go on to develop spinal cord compression if they survive long enough. This is due mainly to hyperplasia of the dura and ligamentum flavum and most commonly

**FIGURE 102-52** MPS VI pelvis and hips: underdeveloped acetabula, flattened femoral heads.

**FIGURE 102-53** MPS VI patient aged 12 months. X-rays at presentation illustrate the kyphoscoliosis that can occur in this disorder.

occurs in the cervical region (198) although it can occur at multiple sites along the spinal canal (199). In some patients, the odontoid will be dysplastic and decompression will need to be followed by occipitocervical fusion. Figure 102-56 illustrates the typical cervical MRI scan findings in MPS VI.

A 15-year-old patient with rapidly progressing MPS VI is illustrated in Video 102-12. The patient is blind from previous raised intracranial pressure, has a tracheostomy for upper airway obstruction and illustrates the severe joint stiffness seen in the disorder.

A number of mutations are known to be associated with slowly progressive MPS VI (188). Some of

the reported patients can be exceptionally mild and a number would presumably never be correctly diagnosed (200). In general, these patients have slowly progressive bone and joint disease, most eventually develop cardiac valve lesions and some have significant visual problems later in life. Urinary GAG excretion (below 100  $\mu\text{g}/\text{mg}$  creatinine) is much lower than what is seen in rapidly progressing patients and patients can survive into their 50s and occasionally beyond (187). The patient illustrated in Figure 102-55 presented at the age of 14 years to the growth clinic as she had fallen across the height centile chart. Minor radiological abnormalities on skeletal survey prompted investigation for an MPS

disorder and MPS was diagnosed. [Video 102-13](#) shows the same patient carrying out a range of tasks. Apart from her stature, there is little to suggest an underlying MPS disorder.

Patients with an intermediate phenotype usually develop the signs and symptoms seen in rapidly progressing patients but at a later age. In addition, as the skeletal dysplasia is less severe there is never the same degree of restrictive respiratory disease, allowing for much longer survival.

**FIGURE 102-54** MPS VI fragmentation of left acetabular head (arrow).

**FIGURE 102-55** Slowly progressive MPS VI patient aged 14 years.

### 102.10.1 Treatment of MPS VI

Historically, the treatment of MPS VI was palliative with surgical treatment for upper airway obstruction, spinal cord compression, corneal clouding and nerve entrapments. Like other MPS disorders, this is best provided in major centers with full access to the multidisciplinary care necessary for successful management.

HSCT was introduced as a treatment for rapidly progressing MPS VI in 1984 ([201](#)) and led to widespread clinical improvements in the treated patient who went on to survive at least 20 years following the transplant with a good quality of life ([202](#)). A review of HSCT in MPS VI reported mainly on safety of the procedure and not clinical outcome ([203](#)). In 45 MPS VI patients identified in the study, the probability of survival was 78% (65–89%) at 100 days and 66% (52–79%) at 1 and 3 years. The main causes of death were infection (44%) and organ failure (31%). Many of the transplants were performed over 10 years ago (latest 2007) and it is uncertain how relevant the safety data would be when compared with HSCT performed from 2010 onwards.

In terms of clinical outcome, long-term follow-up of UK patients documented improvements or stabilization of cardiac function but progression of skeletal disease ([204](#)).

**FIGURE 102-56** Intermediate MPS VI in a male child aged 6 years.

Since the introduction of ERT, HSCT is no longer recommended as the therapy of choice by the majority of treating centers.

The development of ERT for MPS VI has been greatly helped by studies on a cat model of the disease (205). These have demonstrated the importance of early treatment (206) and also the possibility of using enzyme therapy to treat both joint disease (207) and dural hyperplasia (208).

Human recombinant *N*-acetylgalactosamine 4-sulfatase (rh4S, Galsulfase, [Naglazyme™, BioMarin Pharmaceutical Inc., Novato, CA]) is licensed for the treatment of all forms of MPS VI. In an initial Phase I/II clinical trial, there were no drug-related serious adverse events or infusion associated reactions. The treatment was well tolerated and there was a rapid fall in urine GAG as well as an improvement in a 6-min walk test and shoulder range of movement (209). Additional improvements in endurance, mobility and joint function after 48 weeks of treatment were observed in the same group of patients (210).

A subsequent Phase III, randomized, double-blind and placebo-controlled study in 39 MPS VI patients confirmed efficacy with significant improvements in endurance (211). Subsequent long-term follow-up of this cohort of patients over a 5-year period confirmed sustained improvements over time (212). Subsequent data analysis on the same group of patients has reported improvements in long-term pulmonary function (213) and growth (214).

Like other MPS disorders, the best results from ERT in MPS VI are likely to be seen in patients treated from a very young age (215). Intrathecal ERT has also been used, unsuccessfully, in a patient with pachymeningitis cervicalis (216).

Naglazyme™ is given by weekly intravenous infusion (1 mg/kg) and can safely be given in the patient's home (126).

### 102.11 MUCOPOLYSACCHARIDOSIS VII (SLY SYNDROME, MPS VII)

Mutations in the *GUSB* gene on the long arm of chromosome 7 (7q21.11) lead to a deficiency of the enzyme  $\beta$ -glucuronidase and an accumulation of the GAGs DS, HS and chondroitin-4,6-sulfate. Accumulation of these partially degraded GAGs results in the very rare MPS disorder, MPS VII or Sly syndrome. The disorder is very rare (<1:1,000,000 live births) and less than 50 case reports exist in the literature. The prevalence may be underestimated as the commonest presentation is an antenatal form that presents as nonimmune hydrops fetalis and the diagnosis in these patients may be missed. Certainly, the diagnosis should be considered in families where there is a history of recurrent fetal hydrops (217).

In patients who survive the prenatal period, the disorder is very heterogeneous ranging from a severe neonatal presentation with coarse faces, macroglossia, hepatosplenomegaly and cholestatic jaundice (218) to

an attenuated disorder with survival well into adult life (219). Numerous mutations have been identified in the *GUSB* gene and are presumably responsible for the heterogeneity seen in the affected patients (220).

Cognitive impairment is a feature of all variants of MPS VII and radiological investigations reveal typical changes of DM. Craniovertebral instability with spinal cord compression has also been described (221).

The diagnosis is suggested by demonstrating abnormal GAG excretion in the urine followed by  $\beta$ -glucuronidase assay in white blood cells.

Treatment is generally supportive although HSCT would be a potential treatment for early diagnosed patients. BMT in a 12-year-old patient (diagnosed at 1 month of age with a severe neonatal presentation) led to motor improvements and reduced respiratory infections but no improvement in cognitive abilities (222).

Animal models of MPS VII have been used extensively to assess the possibility of gene transfer as a therapy for MPS disorders (223).

### 102.12 MUCOPOLYSACCHARIDOSIS VIII

The designation was given to a single patient with a presumed deficiency of *N*-acetylglucosamine-6-sulfate sulfatase. The disorder has not been confirmed, and the entry is left open (OMIM # 253230, (224)).

### 102.13 MUCOPOLYSACCHARIDOSIS IX (NATOWICZ SYNDROME, MPS IX)

The disorder has been reported in two families and is caused by the deficiency of hyaluronidase 1, one of two hyaluronidases degrading HA (hyaluronan). In the first patient, clinically the defect led to the development of multiple periarticular masses, which were painful during exertion or febrile illness. Other manifestations in the patient included a flattened nasal bridge, submucous cleft palate, and short stature appearing in later childhood. Radiographs showed intra-articular soft-tissue masses, and acetabular erosions in the pelvis, but no signs of DM (225). In the second family the presentation was compatible with a diagnosis of juvenile idiopathic arthritis (229).

Urinary GAG and oligosaccharide excretion is normal in MPS IX, serum HA is increased and there is a deficiency of hyaluronidase activity in plasma. Histology reveals intralysosomal storage of undegraded hyaluronan in synovial histiocytes and skin fibroblasts.

Subsequent studies in the patients demonstrated mutations in *HYAL 1* one of three genes (*HYAL 1*, *HYAL 2*, *HYAL 3*) that play a role in HA metabolism (226). A mouse model of MPS IX (*HYAL 1*) exhibits osteoarthritis (227) and *HYAL 2*-deficient mice have skeletal dysplasia and thrombocytopenia (228). The human equivalent of *HYAL 2* deficiency has not yet been reported and presumably *HYAL 3* deficiency is likely to have a similar phenotype.

## APPENDIX A SUPPLEMENTARY DATA

Supplementary data related to this article can be found online at <http://dx.doi.org/10.1016/B978-0-12-383834-6.00107-5>.

**VIDEO 102-1:** (a) demonstrates a normal airway and (b) the typical progressive changes seen with age airway in an MPS IH patient as seen down a rigid and fiberoptic bronchoscope.

**VIDEOS 102-2 AND 102-3:** These videos show a 4-year 4-month-old MPS IH patient interacting with her physical therapist. The typical facial features, abdominal distension and joint contractures are all clearly demonstrated.

**VIDEO 102-4:** This video illustrates a 15-year-old MPS IH patient treated by BMT at the age of 18 months. He is short in stature, has residual joint stiffness and has problems with dexterity secondary to his hand abnormalities. Despite these difficulties, he is able to cope well with most tasks and attends a normal school.

**VIDEOS 102-5 AND 170-6:** These are two short videos of two patients with MPS IH/S demonstrating the difficulties with dexterity. In Video 102-6 note the exaggerated lordosis.

**VIDEOS 102-7 AND 102-8:** These videos illustrate two 17-year-old Scheie patients performing the same tasks as the MPS IH/S in Videos 102-5 and 102-6.

**VIDEO 102-9:** This video illustrates the characteristic breathing during sleep in a young patient with MPS II.

**VIDEO 102-10** Severe nocturnal agitation in an MPS III patient. The cause of such a presentation is often unclear.

**VIDEO 102-11:** This video illustrates the typical gait of a young teenager with MPS IVA.

**VIDEO 102-12** A patient aged 12 years with rapidly progressing MPS VI.

**VIDEO 102-13** A 16-year-old girl with slowly progressing MPS IV.

## Biography

**Name:** Professor Ed Wraith

**Qualifications:** MB, ChB, FRCPCH

**Title:** Professor of Paediatric Inherited Metabolic Medicine

**Tel:** ++00 44 (0) 161 7012138

**Fax:** ++00 44 (0) 161 7012303

**E-Mail:** [ed.wraith@cmft.nhs.uk](mailto:ed.wraith@cmft.nhs.uk)

**Special Interest:** Lysosomal Storage Disease

### Profile

Professor Wraith is an Honorary Professor of Pediatric Inherited Metabolic Medicine and Consultant Pediatrician in the Department of Genetic Medicine, St. Mary's Hospital, Manchester, England, where he is responsible for the clinical and laboratory services provided by the Unit. In addition, he is a pediatrician specializing in inherited metabolic diseases and in particular children with lysosomal storage disease. He directs the NCG commissioned LSD service based at the Royal Manchester Children's Hospital.

He was born in the northeast of England, graduated from Sheffield University in 1977 and received his postgraduate qualification in pediatrics (MRCP) in 1980. In 1993, he became a Fellow of the Royal College of Physicians (FRCP) and in 1997 a Fellow of the Royal College of Pediatrics and Child Health.

He has served on the Editorial Board of the Archives of Disease in Children and is an editor of The Journal of Inherited Metabolic Disease. Additionally, he is a medical advisor to the UK Mucopolysaccharide Society and the Niemann–Pick Disease group.

Dr Wraith is currently researching several projects, including enzyme replacement therapy for the treatment of a number of lysosomal storage diseases and the use of substrate reduction therapy in patients with neurodegenerative disease.

He has written over 200 articles, abstracts, and book chapters on topics related to inborn errors of metabolism in neonates, children and adults.

# Oligosaccharidoses: Disorders Allied to the Oligosaccharidoses

Jules G Leroy

Greenwood Genetic Center, Greenwood, SC, USA

## 103.1 OLIGOSACCHARIDOSES

Oligosaccharidoses are a group of inborn errors that adversely affect the catabolism of the glycan parts in glycoproteins and glycolipids. The several inborn errors due to deficient synthesis of these glycans, called congenital disorders of glycosylation (CDGs), are the subject of a separate chapter. The multisystemic clinical features, the progressive natural course, and the cellular and chemopathology findings prompted the concept of lysosomal storage disorder (LSD) as an initial characterization of the common pathogenesis. Not all oligosaccharidoses are true LSDs although excessive oligosacchariduria is the common hallmark. The ever more impressive physiologic importance of N- as well as O-glycosylation in intermediary metabolism explains the diseases' multisystemic nature that includes the central nervous system (CNS).

The term oligosaccharidosis (OS) has been aptly substituted for the initial name mucopolidosis (ML) that stressed the clinically challenging relationship between the oligosaccharidoses on the one hand and the mucopolysaccharidoses (glycosaminoglycan storage disorders) and lipidoses on the other hand.

Because of their adverse effect on glycoprotein catabolism due to either primary or secondary deficiency of lysosomal glycosidases or proteases, the term glycoproteinoses would be an adequate alternate to this chapter's title.

Table 103-1 lists the disorders discussed in this chapter that more or less fit the definition of OS. In all, the specific enzyme defect is known. In all, the mutant gene has been sufficiently characterized in order to make specific mutation screening the optimal method for formal confirmation of the clinical diagnosis.

Section 103.2 treats a heterogeneous group of metabolic disorders, once rightly or wrongly considered allied with oligosaccharidoses. The results of the more recent investigations show more clearly that the pathogenesis is

at least indirectly a lysosomal one. See the listing in Table 103-2 pertaining to Section 103.2.

Each one of the oligosaccharidoses is inherited as an autosomal recessive trait with the recurrence risk of one in four for full sibs of probands. As causal or truly effective treatment is still lacking, management of the disorders remains in the realm of preventive medicine. Paradoxically, this prevention finds its retrospective foundation in early diagnosis in the proband and requires genetic counseling and prenatal diagnosis as measures of practical strategy. Fetal monitoring by either relevant enzyme assay or mutation screening in chorionic villi or in cultured amniotic fluid cells is available and is reliable. Elective abortion remains one of the options to parents within the flow sheet of preventive measures.

### 103.1.1 Sialidoses

The term sialidosis (MIM # 256550) should be reserved for the clinical conditions due to the primary deficiency of lysosomal glycoprotein sialidase (MIM # 608272). Four nosological entities had been discerned clinically under the common name sialidosis (Table 103-1) before the elucidation of the enzyme defect and the molecular characterization of *NEU1*, the gene encoding acid sialidase, also known as neuraminidase 1 (NEU 1) (MIM # 608272). The entities delineated still serve as points of reference in what is gradually emerging as a continuous phenotypic spectrum by the reports of more patients and the characterization of the *NEU1* mutations causing their illness.

#### 103.1.1.1 Clinically Delineated Phenotypes.

**103.1.1.1.1 Childhood Dysmorphic Sialidosis or Sialidosis Type II.** Originally called lipomucopolysaccharidosis on its clinical delineation, childhood dysmorphic sialidosis (CDS) was subsequently named ML I. In many reviews, this sialidosis with gradually coarsening facial features from early childhood has been called Sialidosis type II, whereas in these sources the

TABLE 103-1 Oligosaccharidoses

Phenotype		Gene			Enzyme		
Group Entity (Synonym)	MIM#	Gene	Genome Location	MIM#	Defect	Symbol	EC#

<sup>a</sup>CRSM: Cherry-red spot myoclonus syndrome.<sup>b</sup>Group of disorders discussed in the chapter on lipidoses.

disorder with adolescent onset is known as Sialidosis type I (1).

The onset in early childhood and the slowly progressive natural course set CDS apart from either the congenital and early infantile subgroup of patients with more aggressive disease or the juvenile normosomatic sialidosis that are discussed below. Coarse facial features, slow psychomotor development, and thoracolumbar kyphosis are noticed in early childhood. Inguinal herniae may be present before other findings prompt metabolic studies. Also, sensorineural deafness is a feature from early childhood. Facial puffiness, low nasal bridge, bulbous nose with anteverted nostrils, mildly hypertrophic gums, and broad maxilla are reminiscent of what is seen in the patient with Hurler disease (Mucopolysaccharidosis IH: MPS IH; MIM # 607014). The teeth are widely spaced and the tongue is enlarged. Intellectual development and statural growth are slower than normal. Height is below the third centile from 3 to 5 years of age. The thoracic cage is barrel shaped with pectus excavatum and some asymmetry due to mild or moderate kyphosis. Neuromuscular signs becoming more apparent after the age of 10 years include progressive ataxia, nystagmus,

strabismus, muscle wasting, and worsening weakness. The motion range in the small joints of the hands stays intact and the limitation of large joint movements is only mild. By then, ophthalmologic examination for complaints of decreasing vision reveals a macular cherry-red spot and inconsistent cataract and some corneal opacity. CDS patients become chair bound by or even before adolescence. The appearance of a coarse tremor and bouts of myoclonic jerks compound the neurologic syndrome. Peripheral neuropathy is documented by finding decreased nerve conduction velocity. Intellectual disability is a consistent feature, but true intellectual deterioration has not been reported. Fatal outcome in adolescence or early adulthood relates to adverse complications of the neurologic syndrome, pneumonia, and/or cardiomyopathy often insufficiently studied in the older CDS patient. α-Mannosidosis is an alternate differential diagnosis in the older CDS patient, especially when retinal changes and peripheral nervous system disease are absent.

Radiographically, the skeletal manifestations in CDS remain subtle and progress to only mild dysostosis multiplex (1).

**103.1.1.1.2 Juvenile (Adult) Normosomatic Sialidosis; Cherry-Red Spot Myoclonus Syndrome; Sialidosis Type I.** Almost simultaneously with the discovery of the primary metabolic defect in CDS, the specific activity of the same glycoprotein acid sialidase was found to be deficient also in the cherry-red spot myoclonus (CRSM) syndrome that accordingly was named sialidosis type I.

The initial complaints in adolescent or young adults concern gait difficulties and/or declining visual acuity. The designation CRSM syndrome adequately refers to the main clinical features in the fully developed disorder: slowly progressive reduction of visual acuity, first evident in some instances before 10 years of age, and a crippling, often generalized action myoclonus sometimes appearing from as early as the onset of the second decade of life. Demonstration of the macular cherry-red spot is rarely concomitant with the initial complaints about the vision deficit. A long time lag may exist between the onset of reduced vision and that of myoclonus. Seizures not associated with the loss of consciousness are shown to be repetitive bursts of generalized severe myoclonus, but not always promptly recognized as such. Nystagmus, dysarthria, and mild ataxia may become additional components in the syndrome. Muscle weakness, atrophy, and also neuropathy have been documented in juvenile (adult) normosomatic sialidosis (JNS), thereby providing also a physiopathologic link between JNS (CRSM syndrome) and CDS. It needs pointing out that intellectual disability and skeletal dysplasia changes are absent in JNS. For the issue of clinical differentiation from the late-onset type of galactosialidosis, the reader is referred to [Section 103.1.7](#). For references to the early reports on sialidosis, the reviews by Leroy (1) and by Thomas (2) may be consulted.

#### **103.1.1.1.3 Early-Onset Sialidoses.**

**103.1.1.1.3.1 Congenital Nonimmune Hydrops; Perinatal Sialidosis.** Acid sialidase deficiency has been shown to result also in hydrops fetalis in the prematurely born or the at-term neonate. The infant is small for date, but clearly hydropic with extensive edema, massive ascites, and hepatosplenomegaly. There may be pleural effusion and signs of life-threatening cardiorespiratory failure. Supportive measures in the neonatal intensive care unit may be only transiently effective. Fatal outcome often occurs within the first days or weeks of life. Usually, there is evidence that the hydrops had an in utero onset (3,4).

Neonatal nonimmune hydrops is far from pathognomonic for early-onset type sialidosis. It may result from the deficiency of almost any one of the lysosomal glycosidases (5). Therefore, samples for metabolic and enzymatic diagnostic work-up should be taken. Postmortem examination is strongly advisable. The generalized cytoplasmic vacuolization and more detailed EM findings in any parenchymatous organs and connective tissue cells including cultured fibroblasts support the diagnosis of any lysosomal enzyme deficiency. Study of sialyloligosaccharides (SOSs) or other macro compounds in urine or other body fluids using advanced analytical methods should orientate or

complement the assay of lysosomal enzymes in cultured fibroblasts.

**103.1.1.1.3.2 Infantile Sialidosis and Nephrosialidosis.** Sialidosis has also been diagnosed in young infants with only minor or transient edema or without any sign of postnatal hydrops. The patients are physically normal at birth except for mildly coarse facial features that may remind the examiner of features in the early-onset mucopolysaccharidoses. Visceromegaly is present and dysostosis multiplex is gradually evident in skeletal radiographs. Growth rate remains subnormal. There is no macrocephaly and joint mobility is only minimally affected. Only in some of these patients, a rapidly evolving glomerular nephropathy has been documented. Such observation in 1978 was the basis for Maroteaux terming the disorder in these infants nephrosialidosis (MIM # 256150). The rather fulminant kidney disease is soon fatal. Without the adverse renal component, the further clinical course of infantile sialidosis (IS) is indistinguishable from that of CDS.

**103.1.1.2 Cyto- and Chemopathology.** Peripheral lymphocytes contain large vacuoles and the histiocytes in bone marrow smears have a foamy cytoplasm. These findings are less consistent in JNS. Electron micrographs of these cells show enlarged, membrane-bound vesicular, lysosome-like organelles enclosing the reticulogranular material that fills the major portions of the cytoplasm. Similar histopathologic changes are found in Küpffer cells and hepatocytes as well as in neurons and mesenchymal cells.

Urinary excretion of several SOSs and sialylglycopeptides is excessive. The sialyl moieties occupy the terminal nonreducing position. Quantitatively, the excessive excretion of SOSs is more extreme in the infantile types of sialidosis and less pronounced in JNS. As the enzyme-based or mutation screening-based diagnosis may be delayed until adulthood in the latter type, oligosacchariduria may no longer be detectable. When studied by routine analytical methods, urinary excretion of SOSs is qualitatively similar to or indistinguishable from that observed in patients with galactosialidosis or with GlcNAc-1-phosphotransferase deficiency disorders. By more advanced and not routinely available analytic and spectroscopic techniques, qualitative differences between the SOSs excessively excreted in the urine can be demonstrated (6,7).

Free sialic acid is near or completely normal in the urine of the sialidosis patients, where it is bound to partly degraded glycoproteins and glycolipids. This negative result pleads against the diagnosis of a sialic acid storage disorder (SASD) or sialuria (see [Section 103.2](#)). Storage products in CDS brain include lipid-(mainly ganglioside-) bound and protein-bound sialic acid. Accumulation of free and bound sialic acid in sialidosis fibroblast strains matches the one in I-Cells and in galactosialidosis fibroblasts (see subsequent sections).

Since the advent of mutation screening adequately oriented by the clinical diagnosis, chemopathology data

have become ancillary at best in formally establishing the diagnosis.

**103.1.1.3 Lysosomal Acid Sialidase: Primary Enzyme Defect and the Role in Diagnosis.** Somatic cell hybrids between CDS and JNS or early-onset sialidosis fibroblast strains constructed in the 1980s failed to metabolically complement one another providing in vitro evidence that all types of sialidosis are due to functionally allelic mutations. The biochemistry-based diagnosis of sialidosis involves not only the demonstration of a significantly deficient glycoprotein sialidase in fresh leukocytes, cultured fibroblasts, amniocytes, or postmortem tissues. It requires, in addition, establishing in these cells or tissues that  $\beta$ -D-galactosidase is normally active (see further sections in this chapter). Sialidosis has been diagnosed prenatally by enzyme assay (4). In parents of the patients, the expected intermediate sialidase activity has been found in fresh leukocytes or cultured fibroblasts. Acid sialidase activity is destroyed by freezing.

Sialidase 1 (EC 3.2.1.18) or neuraminidase 1 (NEU1; molecular mass: 76kDa; 425 amino acids) belongs to the small family of NEUs widely distributed in nature. Besides its involvement in the cellular immune response, the enzyme catalyzes the intralysosomal hydrolysis of ketosidically linked sialic acid residues in glycoconjugates (Figure 103-1). NEU1 is the most widely and intensely expressed mammalian sialidase in all cell types. Hence, its absence generates the multisystemic disease sialidosis in man and in NEU1<sup>-/-</sup> mouse models (see next paragraphs).

Already, the original purification procedure provided proof that the enzyme occurs in a macromolecular complex of proteins that also encompasses a protective protein with its own cathepsin A (CA) activity (CTSA; OMIM # 613111) and  $\beta$ -D-galactosidase (GLB1; OMIM # 230800). Soon after biosynthesis, nascent sialidase forms a heterodimeric structure with the protective protein in the larger protein complex and thus ensures its effective trafficking to the lysosomal compartment and intralysosomal stability and activation (8). Heterodimerization with the chaperone-type CTSA prevents premature oligomerization and degradation (9–11).

**103.1.1.4 Studying Mouse Models Relevant to Pathogenesis.** The disease that develops in NEU1<sup>-/-</sup> mice is also multisystemic and similar to severe human sialidosis. The affected animals develop progressive splenomegaly with extramedullary hematopoiesis. Yogalingam et al. have recently demonstrated that NEU1 controls sialylation in the hematopoietic cells and the concomitantly normal turnover of lysosomal-membrane associated protein 1 (LAMP1). Hyper-sialylation of LAMP1 at the lysosomal membrane prompts preferential docking of lysosomal organelles onto the plasma membrane (PM) and their exocytosis. Excessive exocytosis of lysosomal enzymes such as serine proteases leads to the premature degradation of vascular cell adhesion molecule 1 and loss of bone marrow cells (10).

Abnormally intense exocytosis is likely to have additional effects in sialidosis. Oversialylation, increased expression of LAMP1 and other LAMPs, and their apical localization in the marginal cells of the stria vascularis in the mouse cochlea suggest that there is excessive exocytosis into the endolymph with failure to adequately transduce sound through the sensory hair cells (12). Moreover, increased exocytosis from fibroblasts may represent at least one of the mechanisms underlying progressively abnormal remodeling of the extracellular matrix (ECM) and the overproliferation of the connective tissue (13) relevant to the coarsening of facial features and possibly to the bone dysplasia in early-onset and severe sialidosis. The expanding connective tissue around and within muscle fibers leading to their dysfunction and ultimate loss is likely to have a similar basis. Muscle weakness and atrophy are known to become prominent in long surviving patients. Thus, the mouse model studies reveal that sialidosis is an inborn error of metabolism in which lysosomal exocytosis is exacerbated (8,10).

**103.1.1.5 NEU1 Encoding Sialidase and Formal Diagnosis by Mutation Screening.** The gene encoding lysosomal sialidase, called NEU1 (OMIM # 608272) is located on the short arm of human chromosome 6 at 6p21.3 and hence within the large genomic site harboring the major histocompatibility gene loci. NEU1 contains six exons and spans about 3.8kb of genomic DNA. The gene and its encoded protein, the most abundant and most widely expressed mammalian sialidase, have considerable homology with other NEUs, including homology with the enzyme from the most divergent sources in nature such as some well-characterized bacterial sialidases (8).

Mutation screening has become the preferred method for formal confirmation of the diagnosis since the molecular characterization of NEU1. Over 40 different mutations have been identified in either homozygous or compound heterozygous genotypes in patients with any of the various types of sialidosis. Studying the correlation between the phenotype and the mutant genotype has yielded the expected result in most patients with severe diseases, where often at least one nonsense mutation or one mutation that impacts the reading frame (Frame Shift: FrSh) is revealed. The phenotypes are associated with complete absence of sialidase activity and the latter mutations are termed phenotypically “null” or “amorph.” The report of the amorph effect of a homozygous large 11kb interstitial deletion that had removed the entire NEU1 coding region is a case in point (14). Early-onset severe disease was also the clinical effect of the homozygous splice-site mutation that deleted the exon 5 completely (15) or of homozygous or compound heterozygous nonsense mutations with the effects of protein truncation and the complete loss of enzyme activity (16). If such amorph mutation is accompanied by a NEU1

**FIGURE 103-1** “Wild-type” lysosomal degradation pathway of complex *N*-glycans in glycoproteins, including lysosomal hydrolases, proceeds simultaneously on both the protein and the glycan components. *N*-glycans are degraded sequentially by the lysosomal hydrolases (mainly exoglycosidases). Deficiency of one hydrolase causes accumulation of the substrate involved and adverse effects on other catabolic steps. (Figure reproduced from Freeze, H. H. *Genetic Disorders of Glycan Degradation*. Chapter 41, pp. 567–583, Figure 41.1, In: *Essentials of Glycobiology*, 2nd ed.; Varki, A. et al., Eds.; CSHL Press: Woodbury, NY, 2009, with gratefully acknowledged permission by the editors and the publisher.)

missense type, called hypomorph, considerable residual sialidase may be detectable in the patient with late-onset, mild JNS.

In addition to the molecular type, also the location of mutations within *NEU1* is a challenging factor for predicting the phenotype associated with missense (MS) mutations located in the periphery of the tridimensional protein. Some of the latter adversely affect the binding of sialidase to its protective chaperone, PPCA (protective protein CA), and within the larger quaternary ( $\beta$ -D-galactosidase, CA, sialidase (GCS)) protein complex (16,17).

Sequence analysis and homology alignment methodology with other mammalian sialidoses have contributed to the tridimensional model building of the wild-type enzyme (18,19). It has turned out to be helpful in predicting the impact of MS mutations also on the enzyme's normal subcellular trafficking and location and on the concomitant biochemical maturation as studied by immunohistochemical methods (17). Among others, Seyrantepe et al. (16) have proposed to subdivide sialidase MS mutations into three groups: (1) mutations substituting amino acids within the enzyme's catalytic site and having a severe effect and an early onset; (2) mutations in the periphery of the enzyme without any major effect on the tertiary structure with the mild late-onset type clinical disease; (3) MS mutations located at the periphery of sialidase, but located within peptides necessary for binding into the quaternary GCS complex. The latter consistently result in early onset and severe disease.

### 103.1.2 Disorders due to the Deficiency of $\beta$ -D-Galactosidase

The disorders due to the acid  $\beta$ -D-galactosidase deficiency known as the various types of  $G_{M1}$ -gangliosidosis are discussed in the chapter on lipidoses. The term gangliosidosis implies only defective ganglioside metabolism and lysosomal storage of gangliosides with progressive CNS disease mainly due to neuronal cell death. It is hardly applicable to patients with Morquio type B disease with a rather specific spondyloepiphyseal dysplasia as the main or sole clinical consequence. See Chapter 102.

Patients with these disorders have excessive urinary excretion of OSs with  $\beta$ -galactose at the terminal non-reducing end. The diagnosis is confirmed by finding a severely deficient acid  $\beta$ -D-galactosidase (EC 3.2.1.23) (Figure 103-1) in leukocytes or cultured fibroblasts and a normal specific activity of acid sialidase. Adequate function of  $\beta$ -D-galactosidase is dependent on the intact structure and function of other proteins, notably their protecting and activating factors (next section in this chapter). The gene *GLB1* encoding  $\beta$ -D-galactosidase (OMIM # 611458) has been mapped to chromosome location 3p21.33. A steadily increasing number of mutations, single nucleotide substitutions, and larger structural

rearrangements have been identified. The clinical effect of progressive brain disease is most often severe and is evident from early infancy, occasionally expressed from late infancy or toddler age, and rarely first apparent from young adulthood. *GLB1* has at least two mRNA transcripts due to alternative splicing. Besides the encoding of  $\beta$ -D-galactosidase, it also yields an mRNA species with the genetic code for the catalytically inactive elastin binding protein (EBP) with a role in elastic fiber production.

### 103.1.3 Galactosialidoses

The term “galactosialidosis” is applied to a group of allelic lysosomal disorders due to mutations in the gene encoding the lysosomal protective protein cathepsin A (CTSA) resulting in the combined deficiency of both  $\beta$ -D-galactosidase and acid sialidase as the main metabolic consequence. Clinically and biochemically, the disorders resemble the age of the onset of the matched types in sialidosis (Section 103.1.1) and  $G_{M1}$ -gangliosidosis (Section 103.1.2 and Chapter 104). Moreover, the early-onset type of galactosialidosis represents a diagnostic challenge in discerning it clinically from ML II (see Section 103.1.4).

The juvenile (adult) type of galactosialidose (GS) mostly reported from Japan is the most frequent entity worldwide, but also late infantile GS (IGS) and even non-immune perinatal hydrops due to congenital GS (CGS) have been reported. In the large majority of cases, galactosialidosis is a severe disease most often with protracted natural course. Based on the increasing number of clinical reports, GS represents overall a continuum of phenotypes with the frequency distribution skewed toward late childhood or adolescent age of onset and slow rate of progression.

#### 103.1.3.1 Phenotypes Delineated.

**103.1.3.1.1 Congenital Galactosialidosis.** Congenital galactosialidosis presents as non-immune “hydrops fetalis,” which requires immediate intensive neonatal care that may be unable to prevent fatal outcome. The hydrops already recognized ultrasonographically in the third trimester of pregnancy (20) are often associated with polyhydramnios and hydropic placenta. The often prematurely born neonate is heavy for dates, but short and may have congenital inguinal herniae. In addition to the pronounced and extensive edema, there is hepatosplenomegaly, ascites, and inconsistent pleural effusion. The corneae are cloudy. The macula may be grayish or may already show a small central red spot. There is often proteinuria, anemia, and thrombocytopenia. Cytoplasmic vacuolization is a consistent finding in peripheral lymphocytes. In longer survivors, failure to thrive, refractory to management, and poor neuromotor developments are common. Cardiorespiratory failure compounded by sepsis is often the cause of death in the neonatal period or somewhat later in infancy (20,21).

Fetal loss late in pregnancy has also occurred in families with hydropic CGS. The pathogenesis in this and other genetic types of nonimmune hydrops remains poorly understood since some infants with proven CGS do not show significant edema at birth, but instead start a slowly progressive disease course indistinguishable from that in children with the late infantile type of GS.

The longer surviving patients initially show discrete signs of dysostosis multiplex. This type of skeletal dysplasia is consistently less pronounced than in patients of similar age with either infantile  $G_{M1}$ -gangliosidosis type I or ML II (see next section). The clinical syndrome in a surviving CGS patient is soon indistinguishable from the IGS phenotype.

**103.1.3.1.2 Late Infantile Galactosialidosis.** Only a few patients with clinical onset of GS during or before the second year of life have been reported. Clearly, in at least some of them, the true clinical onset in early infancy had not been recognized. Hence, CGS and late-onset IGS only represent points of clinical reference within the continuously variable, early, but severe GS. The face is slowly coarsening. Statural growth velocity gradually decreases. Head size remains proportional to body size. Failure to thrive is a common complaint. There is corneal clouding at least by slit-lamp examination. Macular cherry-red spot is at first inconsistent. Hepatomegaly is moderate, splenomegaly mild. There is developmental delay and neuromotor progress is slower than normal. In long survivors, cognitive deficiency resembles that in patients with adolescent or adult-onset GS as is true also for the skin changes. Thickening of the cardiac valves and later mild cardiomegaly and cardiomyopathy are consistent features. The rate of clinical progression is remarkably heterogeneous in IGS. Respiratory infections recur often, become increasingly more morbid, and ultimately result in very variably timed fatal outcome of this severe disease (22).

**103.1.3.1.3 Juvenile Galactosialidosis: Goldberg Syndrome.** Juvenile or adult galactosialidosis (JGS) (OMIM #256540), the most frequent form of GS with high prevalence reported from Japan may have its clinical onset from mid-to-late childhood until the fourth decade of life. This interfamilial variability of the age of onset is however larger than the intrafamilial one. See references to original reports in (1,22,23). The first patients described with the Goldberg syndrome have been examples of protracted JGS. In the first survey of Japanese patients, JGS had been called galactosialidosis type II. Parental consanguinity has often been recorded. The composite clinical picture resulting from an astute comparison of the fully developed JGS with the similar but milder JNS, known as CRSM syndrome (see Section 103.1.1.1.2), is helpful for both clinical diagnosis and differential diagnosis. It includes (1) slowly progressive axial and appendicular ataxia without nystagmus, tremor, severely handicapping action myoclonus, hyperactive deep tendon reflexes, and peripheral

neuropathy (24); (2) decreasing visual acuity and macular red spot, corneal clouding often detectable by slit-lamp examination, and infrequently lens opacities; (3) moderate short stature, coarsening facial features, and platyspondyly in the thoracolumbar spinal column as the main expression of otherwise mild dysostosis multiplex; and (4) initially mild, but gradually moderate with a clear mental impairment. The latter two among the four component groups are consistently absent in JNS. Therefore, the designation “cherry-red spot myoclonus syndrome plus” may be an alternate term for JGS provided the following remarks are taken into account: Any one of the clinical components may either be of primordial and/or early concern or lacking altogether; in older patients with diagnosis late in the clinical course, several signs and symptoms may be found retrospectively: Angiokeratoma is frequently an example; hepatomegaly is equivocal at worst, and splenomegaly is not observed in JGS patients. As is the case in the early-onset types of GS, cardiac involvement, especially valvular dysfunction and/or cardiomyopathy, combined with intervening infection fatally compound the ever more dreary neurologic syndrome of JGS (22,23,25,26).

**103.1.3.2 Histo- and Chemopathology: Biochemical Diagnosis.** Patients with any type of GS have vacuolated lymphocytes in the peripheral blood smears aligning them not only with sialidosis but also with many other LSDs. Follow-up reports on the neuro-radiology aspects of GS remain unavailable. Reports on postmortem neuropathology have not been added to the literature in the past decade. Marked atrophy of the brain has been described to be associated with severe neuronal loss, fibrillary gliosis, and histochemically heterogeneous storage in various parts of the brain, brain stem, spinal cord, and in Schwann cells surrounding atrophic peripheral nerves. Careful studies in mutant mice, although phenotypically not completely congruent to the corresponding human diseases, show various lesions in the brain and the cerebellum that are more extensively affected in the sialidosis than in the galactosialidosis model (27). Ultrastructurally, a variety of single membrane-bound cytoplasmic inclusions, some with granular and others with concentric lamellar shape, is found. Vacuoles are readily apparent also in the cytoplasm of hepatocytes, Küpffer cells, and in epithelial cells of the glomeruli and renal tubuli. Nephropathy has been documented in the final years of chronically evolving late IGS (28). Neither the inclusions seen in cultured fibroblasts from IGS patients nor the ones found in parenchymous organs are distinguishable from the ones encountered in subjects with sialidosis or several other lysosomal enzyme deficiency disorders. In hydropic IGS, there is extensive cytoplasmic vacuolization of the trophoblastic cells in the placental tissue (21), indistinguishable, however, from the findings in the perinatally expressed nonimmune

hydrops due to any other inborn lysosomal disorder. The same applies to the pathology features in parenchymatous organs even in the longer surviving CGS patients (29). The storage adversely affects endothelia especially in the capillaries within angiokeratoma lesions (26). See also Reference (1) for original literature reports.

The storage material in the brain tissue resembles histochemically as well as biochemically the macro compounds accumulated in the CNS and other organs in  $G_{M1}$ -gangliosidosis. However,  $G_{M1}$ - and other ganglioside species are less abundant in GS. The OSs in the accumulated glycoproteins and glycolipids are of the *N*-acetylglucosamine type with the mannose- $\beta$ -1-4 GlcNAc sequence preserved at the reducing ends (Figure 103-1). The structures of the OSs excessively excreted in the urine of GS patients are very variable but similar to the ones found in other OS patients. The combination of several types of chemical analysis (30,31) or advanced analytic methodology is required in order to identify disease-specific features in the body fluids (6,7).

Demonstrating the combined deficiency of  $\beta$ -D-galactosidase and glycoprotein sialidase in fresh leukocytes or cultured fibroblasts provides confirmation of the diagnosis of GS. It needs pointing out that the deficiency of the former enzyme is not found in all tissues and not in plasma. Where detectable, this deficiency is consistently less pronounced than in patients with  $G_{M1}$ -gangliosidosis. In obligate heterozygotes, glycoprotein sialidase activity is intermediate in fresh cells, but  $\beta$ -D-galactosidase is normal. The specific activity of CA by the lysosomal protective protein (PPCA) is at present preferentially assayed and found to be largely deficient in leukocytes and fibroblasts (21). Average values for CA activity are half of normal in obligate heterozygotes. This carboxypeptidase (EC #3.4.16.5) has amply sufficient normal activity in chorionic villi and in amniocytes in order to recommend its assay in a prenatal diagnosis setting. Because of the possibility of a mutation that interferes substantially more with the protective function than with its CA activity, it is advisable to ascertain the coexisting secondary deficiencies of  $\beta$ -D-galactosidase and acid sialidase for confirming the diagnosis, especially in circumstances when or where gene mutation screening is not available.

**103.1.3.3 Molecular Data on CTSA and Its Gene and Formal Diagnosis by Mutation Screening.** Because fibroblast strains from any two clinical types of GS did not show mutual in vitro complementation, the causal mutations were recognized in the 1970s as being functionally allelic before being identified. Immunoprecipitation used in the isolation procedure of the mutant enzymes revealed the existence of a “corrective factor” inactive in GS fibroblasts and tissues, but apparently essential for the adequate catalytic function of

both  $\beta$ -D-galactosidase and acid sialidase. The initially unknown polypeptides of 54, 32, and 20 kDa that coprecipitated with the anti- $\beta$ -galactosidase antibodies were soon identified as molecular species representing the “corrective factor,” because in vitro uptake of the 54 kDa protein promptly normalized the molecular processing of nascent  $\beta$ -D-galactosidase in GS cells. Thus, the primary metabolic defect in GS was elucidated to be the absence or complete deficiency of the 32-/20 kDa two-polypeptide mature protective protein (PP) and/or of its 54 kDa precursor. GS mutant fibroblasts are also deficient in protective protein-specific mRNA. Transient in vitro expression of the wild-type cDNA in COS-1 cells has resulted in the synthesis of the 54 kDa precursor protein, in its conversion into a 32/20 kDa two-polypeptide containing mature enzyme, and its normal routing to lysosomes. Subsequent coprecipitation studies have identified a quaternary multiprotein complex into which the “PP” must enter in order to adequately fulfill its enzyme protective and catalytic role. Not only  $\beta$ -D-galactosidase, but also nascent lysosomal acid sialidase becomes a constituent of this heteromeric protein (GCS) complex while still in the endoplasmic reticulum (ER) in order to avoid premature degradation and to achieve effective intracellular trafficking to and function in the lysosomal compartment (8).

In addition to its protein-protective chaperone-like function, the lysosomal PP has been identified as CA with carboxypeptidase activity at acid pH. Hence, the multifunctional protein is often symbolized by PPCA. At neutral pH, the enzyme can also function as a deaminase/esterase. For routing toward the lysosomal compartment and catalytic function, acid sialidase is totally dependent on integration into the macromolecular protein complex and PPCA integrity, whereas  $\beta$ -D-galactosidase in dynamic equilibrium of its monomeric, homodimeric, and homomultimeric conformations can exist and somehow function independently. The latter applies to the cathepsin A (CTSA) activity of PPCA as well (20).

The multienzyme complex in which PPCA is a protagonist protein contains still other components such as the lysosomal enzyme GalNAc-6-sulfate sulfatase (MIM # 612222), catalyst in the initial step of keratan sulfate degradation and known to be deficient in Morquio disease type A (MPS IVA; MIM # 253000). The urinary excretion of keratosulfate is excessive in GS and even comparable to that in MPS IVA patients. In GS patients, GalNAc-6-sulfatase activity is significantly lower than normal (32).

PPCA also plays an important role in another protein complex called the elastin binding protein receptor (EBPR) located and functional at the PM instead of the lysosomes. It is composed of three subunits, including EBP, PPCA (most often called CTSA), and the *NEU1* gene product, acid sialidase. Also, in this macromolecular

protein complex, PPCA protects the molecular integrity of both EBP and acid sialidase that apparently favors the attachment of the EBPR complex to the PM surface and has also a pivotal role in the secretion and the assembly of tropoelastin monomers into elastic fibers (33).

Beyond its effect in elastogenesis, cathepsin A (PPCA or CTSA), within the PM-bound EBPR complex, is also of regulatory importance in vasoconstriction, blood pressure regulation, and when mutant, a factor favoring the development of the cardiomyopathy in GS that is hardly directly explainable by lysosomal dysfunction. In *Ctsa* gene-targeted mice homozygous for the Ser190Ala MS mutation, located within the active site of the serine carboxypeptidase,  $\beta$ -D-galactosidase and acid sialidase had normal catalytic activity, but cathepsin A was clearly deficient. Further results confirmed that CTSA failed to hydrolyze some regulatory peptides including angiotensin (ang)2 and endothelin1 (ET-1) a peptide of 21 amino acids, most abundantly detectable in endothelia, where CTSA is most strongly expressed. Reduced degradation of ET-1 has been shown spectrophotometrically in the blood and tissue of the mutant mice. The affected animals had a significantly raised arterial pressure. In addition, the role of elastogenesis was confirmed immunohistochemically by finding a decreased amount of elastin containing microfibrils in skin, arterial walls, and lung alveoli (33,34). Paradoxically, elastic fiber formation and EBP mRNA expression studied by immunofluorescence with antitropoelastin antibody and by RT-PCR selective for EBP, respectively, was not significantly different from control values in mutant fibroblasts from either Morquio B patients (*GLB1* gene mutations), galactosialidosis (*PPGB* gene mutations), or sialidosis patients (*NEU1* gene mutations) (35). Either the physical difference between the in vitro ECM in cell cultures and that in tridimensional tissue, or the failing stability of the elastic fibers rather than the formation of the microfibrils containing them may preclude effective comparison of the results reported.

Mutations that adversely affect the posttranslational processing of the CTSA protein have been extensively reviewed by d'Azzo et al. (22). Nascent human CTSA is synthesized as a 480-amino acid precursor protein (54kDa), where Asn 117 and Asn 305 serve as N-glycosylation anchors. The protein contains nine cysteines and accommodates a hydrophobic signal peptide (SP) of 28 amino acids cleaved off upon ER entry, where CTSA is promptly N-glycosylated and dimerizes. While passing through the cis Golgi cisterns only the Asn 117 oligosaccharide acquires the mannose-6-phosphate (M6P) marker, required for proper routing of the dimer to the lysosomal compartment. Following the conclusion of this voyage, the precursor undergoes endoproteolytic cleavage into the 34- and 20-kDa inactive intermediates and a 2-kDa “excision” peptide is subsequently removed from the C-terminus of the larger protein that finally becomes the mature 32-kDa subunit. However, several

disulfide bridges hold the two polypeptides together as a single unit. By the removal of the “excision” peptide, the catalytically active site of the CTSA protein composed of the triad of amino acids serine (S) 150, histidine (H) 429, and aspartic acid (D), becomes exposed. Effective catalysis at the active site depends also on the tridimensional conformation of CTSA and on the integrity of the multiprotein complex in which it plays its multifunctional role (22).

The gene encoding the protective protein CA has received various names abbreviated as *PPCA*, *PPGB*, or *CTSA*, the latter becoming the more official one. It has been mapped to chromosome 20q13.12 and spans about 7.5kb of genomic DNA. It has 15 exons that, except for a short 5' untranslated region (UTR), represent the coding region. The latter is followed by the 3' UTR and the polyadenylation sequence. Human *CTSA* and mouse *ctsa* are very similar including the 5' promotor regions. The protein coding *CTSA* transcript of 2.1kb (one of the six protein-encoding transcripts) is expressed ubiquitously. The protein encoded is predicted to have 498 amino acids.

The clinical heterogeneity of GS is largely surpassed by the number of mutations in the *CTSA* gene with morbid effect in homozygous and compound heterozygous mutant genotypes.

Among the juvenile-onset patients (JGS) reported from Japan, homozygous deletion of the complete exon 7 is frequently found. It is due to the splice-site mutation IVS7, c.A>G, +3→Ex7del. Its late-onset, slow course, and rather mild features remain incompletely understood. The Ex7del mutation is leaky because in the homozygote a small amount of normally spliced transcript is detectable. When this Ex7del mutation is combined either with the MS mutation Trp65Arg (exon 3), the Ser90Leu (exon 3), or the Tyr249Asn (exon 8) (MS mutations), the clinical result is the more severe late IGS. Interestingly, the MS mutation Tyr395Cys associated with the Ex7del mutation in a compound heterozygous genotype yields a GS of intermediate severity. The homozygous Tyr395Cys genotype was found to result in early-onset IGS, where residual enzymatic activity was absent. Lack of phosphorylation of the CTSA protein precludes proper routing to the lysosomes (see next section) and in homozygotes is the primary metabolic consequence of the mutations Val104Met, Leu208Pro, or Gly411Ser. Each of these mutant genotypes results in early and severe IGS. The same clinical effect has been observed in Lys453Glu homozygotes. The latter MS mutation is located at the interface of the PPCA dimer (36).

As expected, some deletions or additions of nucleotides result in the shift of the mRNA reading frame and in the creation of abnormally located stop codons. In the homozygotes with the CTSA protein being at least truncated and often quickly degraded, non-immune hydrops CGS is the consistent clinical outcome. The clinical effect of the single nucleotide C899 insertion in exon 10 in two

unrelated Dutch patients with nonimmune fetal hydrops due to early lethal CGS is an example. The mutation was homozygous in one patient. It was associated with the MS transition c.169G>A in exon 3 (G57S: substitution of a nonconserved glycine) in the other patient. In both infants, the amount of CTSA mRNA was considerably reduced. The insertion of the single cytosine with frameshift effect caused premature termination of PPCA precursor synthesis and the predicted lack of the 20-kDa subunit. Moreover, the remaining mutant protein is being misfolded, fails being incorporated into the multienzyme complex, and cannot be routed to the lysosomes. Both the catalytic activity and the protecting and activating roles cannot be played: hence, the severe clinical consequences (21). In an Italian family with multiplex occurrence of CGS and nonimmune hydrops, two previously unreported CTSA mutant alleles were detected: c.60DelG and IVS2+1G>T. In this genotype, either mutation with different frameshift effect contributed to the complete absence of CTSA and of EBP translated from the alternate mRNA transcribed off the *GLB1* gene. This observation has provided proof of the role played by CTSA in the EBPR complex at the PM, where it coregulates elastic fiber synthesis and suppresses fibronectin production. This study also found interesting genetic polymorphisms in the CTSA (*PPBG*) gene (20). CGS in a prematurely born female with clear signs of fetal hydrops, who died at over 200 days of age due to renal failure, was due to homozygosity for the c.146A>G→p.Gln49Arg MS mutation in exon 1 of the CTSA gene. The mutation had been reported earlier in a compound heterozygous patient with JGS who also carried the DelEx7 splice-site mutation. Given its rare incidence, still too few reports are available describing this severe, most often chronic metabolic disorder. It is unfortunate that often-adequate clinical detail is lacking in the reports most informative regarding the molecular biology of GS. In contrast, in several clinically adequate to excellent papers, no information on the mutant genotype is provided. Future improvement of the genotype-phenotype correlation in GS also awaits more results of thorough studies on its complex pathology.

### 103.1.4 N-Acetylglucosamine Phosphotransferase Deficiency Disorders

#### 103.1.4.1 Clinically Delineated Syndromes.

**103.1.4.1.1 ML II or I-Cell Disease.** ML II is a slowly progressive disorder with clinical onset at birth and fatal outcome in childhood. It may be suspected prenatally when ultrasonographic examination in the last trimester of pregnancy finds punctate extraosseous calcifications around the ankles, wrists, spine, or pelvis in a small-for-date fetus. The neonate with I-Cell disease has on average a low birth weight, a plump and somewhat edematous, flat facies, and a skin that is thick and stiff in particular about the earlobes. Congenital inguinal herniae are

consistently present in males. One or more orthopedic abnormalities are common: clubfoot, dislocation of the hip(s), thoracic deformity, with or without kyphosis. Despite generalized hypotonia, the range of motion in the shoulders is limited. In the more severely affected neonates, crying is weak, respiration may temporarily need support, and alertness is below normal. Head size is proportional to stature. Growth failure is always severe and the final height of 80 cm is rarely exceeded. Unlike in the patient with Hurler disease (MPS IH: MIM # 607014), there is no temporary acceleration of statural growth around the age of 1 year. Instead, growth decelerates within 6 months from birth and ceases often before 15 months of age. Stiffening of all joints, large and small, occurs from the first year of life. Neurodevelopmental delay is severe in some, but more moderate in others. Only few patients come to unaided ambulation. Social interaction is better than the patient's hoarse speech that rarely reaches the stage of two-word sentences. Upper respiratory infection and otitis recur frequently. Hearing deficit that worsens over time is often evident. Breathing is noisy from the start and remains so even in the absence of bronchitis or lung infection. Because of the narrow airway, the gradually decreasing mobility of the neck compounded by hypertrophic gums, both intubation and detubation are difficult assignments for the anesthesiologist. The face of the ML II patients is reminiscent from that in MPS IH, but shows consistent differences including small orbits, hypoplastic supraorbital ridges, mildly proptotic eyes, a tortuous pattern of periorbital veins, telangiectatic capillaries over midface and cheeks, impressive gingival hyperplasia precluding adequate eruption of deciduous teeth, and a prominent mouth (Figure 103-2). The corneae are often considered clear clinically, but slit-lamp examination consistently shows haziness. Facial features are gradually coarsening in the longer-surviving patients and wrists, hands, and fingers broaden, become more immobile, and adopt a clawlike configuration in radial deviation. Cardiac murmurs increase gradually with slowly worsening insufficiency of several cardiac valves. The abdomen is protuberant and an umbilical hernia often noticed. Hepatosplenomegaly is moderate or equivocal. Bronchopneumonia and congestive heart failure are the usual causes of fatal outcome, usually before the age of 5 years. See original reference in Reference (1) and/or in other extensive reviews (37,38).

Affected siblings are clinically more similar than patients in different families.

Qualitatively, the radiological abnormalities in ML II are indistinguishable from the ones in MPS IH (OMIM #) and in G<sub>M1</sub>-type I GS (OMIM # 230500). ML II shares with the latter the most severe form of "Dysostosis multiplex," the osteochondrodysplasia (OCD) common to most oligo- and mucopolysaccharidoses and expertly described by Spranger et al. (39). At this stage, attention is due to some transient radiographic and related phenomena observed in or from the perinatal stage of

**FIGURE 103-2** Clinical manifestations in ML II. (a–c) Patient 1 at 5 years 10 months; (d, e) patient 2 at the ages of 3 months and 20 months; (f, g) patient 3 at 13 months and 3 years; (h) patient 4 and (i) patient 5 both at 3 years; (j, k) patient 6 at 13 months and 3 years. Coarsening of facial features, apparent from infancy, evolves in subsequent few years of life. Common features include flat face with depressed nasal bridge, prominent mouth and gingival hypertrophy, shallow orbits, thick skin, full cheeks, deep infraorbital creases, prominent cutaneous veins, and capillaries on the face. Metopic prominence, which creates the impression of craniosynostosis, is depicted in (b), (h), and (i). Short, broad “claw”-like hands and contractures in knees and ankles are seen in (c). (Figure reproduced from Cathey, S. S.; et al. *J. Med. Genet.* 2010, 47, 38–48, Figure 1, with gratefully acknowledged permission from authors and BJM Publishing Group Ltd, London, UK.)

ML II that include: (1) punctate or dot-like extra-osseous calcifications mainly in hands and feet, but also over the pelvic region and about the spinal column. These puncta, when detectable by prenatal ultrasonography, were initially considered to be the more typical feature in “Pacman” dysplasia (40,41), an OCD that was thought of as sharing features with ML II, but with perinatal fatal outcome. Meanwhile proof has been provided that most instances of Pacman type OCD represent the prenatal expression of I-Cell disease (ML II) (41,42); (2) Excessive periosteal new bone formation alongside the diaphyses of the large tubular bones, a phenomenon also called “periosteal cloaking,” the term used to describe the double outline of the bone cortex in the large tubular bones. The phenomenon is no longer visible from the age of 18 months when the calcified outline seems to coalesce with the diaphyseal cortex (39); (3) Severe diaphyseal

widening in the small tubular hand bones concomitantly rendering the metaphyseal ends very narrow, a process that may last until early childhood (43); (4) Perinatal hyperparathyroidism supported by relevant biochemical findings in plasma (42,44). It is unknown at present whether hyperparathyroidism represents the true cause of the transient bony abnormalities or the consequence of an as-yet unknown effect of the mutant genotype set in motion at or before birth. Also, the transient nature of the described set of phenomena awaits pathogenetic explanation.

In patients with ML II, the urinary excretion of SOSs is excessive and that of glycosaminoglycans (GAGs) is normal. This finding is nonspecific as it is hardly distinguishable from the results in urine from patients with sialidosis (Section 103.1.1) or galactosialidosis (Section 103.1.3), when studied by routine laboratory methodology. More

advanced technology, not commonly available, is able to improve chemical differentiation (6,45,46). At present, the latter methodology has interesting potential in more effective newborn screening, but has become of secondary importance in the field of diagnosis since the introduction of mutation screening.

**103.1.4.1.2 ML III $\alpha$ / $\beta$ ; Pseudo-Hurler Polydystrophy.** Delineated and named Pseudo-Hurler polydystrophy (PHP) by Maroteaux in 1966, it was called ML III by Spranger and Wiedemann in 1970 before its alignment with ML II was proved. Since the elucidation of the enzyme defect and of its oligomeric structure, it has been shown that two nonallelic types of PHP exist. The nomenclature has been adapted accordingly (47). In addition to ML III $\alpha$ / $\beta$  at hand, there is ML III $\gamma$ , the subject of the next paragraph.

Complaints of physical slowness, worsening stiffness in one or more of the large joints, and sometimes slow growth around the average age of 3 years mark the clinical onset. Slow cognitive development is rarely among the initial parental concerns. ML III $\alpha$ / $\beta$  patients retain family facial characteristics, but the facies is rather flat and coarsens gradually throughout the long and slowly progressive clinical course. Motion range, particularly in shoulders and hips, is reduced from the early stages of the disorder. The slowly progressive flexion contractures in hips and knees are evident early in the standing patient viewed from the side. Raising the arms above the head is difficult and soon impossible. Birth weight and length are normal in ML III, but below average and gradually decreasing statural growth rate is evident in childhood. The head circumference remains proportional to stature (Figure 103-3). The corneae are clear by clinical inspection, but show opacities on slit-lamp examination. Liver and spleen are not usually enlarged. Intellectual deficiency is mild and nonprogressive or absent. Speech and language development are normal. In the patient with later clinical onset of the disorder, the diagnosis may be postponed because of earlier referral to and follow-up in the rheumatology clinic. The early radiographs may show only mild dysostosis multiplex and are sometimes read as normal. However, skeletal age is found to be considerably delayed and moderate osteopenia already noticed. Contrary to the severe OCD in the hands of ML II patients, the hand bones themselves remain normal or near normal, but the progressive hardening of the soft connective tissue around the small joints results in worsening flexion contractures in the fingers. Already from preadolescence, ML III $\alpha$ / $\beta$  patients consistently have moderate but often severe and very painful hip disease. It is an almost consistent reason why the patients cease walking on average from the early teens. Unfortunately, the pain is not effectively dealt with even in the more immobile wheelchair-bound patient, because it results not only from the destructive hip dysplasia, but also from worsening osteopenia throughout the skeleton. In the older patients, the deficient function of some of the

heart valves apparently due to connective tissue hardening, becomes of increasing concern. Throughout the clinical course, respiratory infections are not significantly more frequent than in the patients' peers, unlike their morbid role in ML II. ML III patients surviving beyond the fifth decade of life have been reported, but comprehensive data on life expectancy and on specific causes of fatal outcome remain unavailable.

The distinct dividing line between ML II and ML III $\alpha$ / $\beta$  has been documented in a recent large genotype–phenotype correlation study supported by the results of mutation screening (43). Significant clinical differences include growth rate and final statural height, hand abnormality, qualitative differences of dysostosis multiplex, neuromotor and speech and language development, intellectual functioning, rate of clinical progression, and life expectancy. The rather rare phenotypically intermediate patients have specific mutant genotypes. See subsequent paragraphs on molecular genetics.

**103.1.4.1.3 ML III $\gamma$  (PHP).** Because the first report on the molecular basis of an ML III $\gamma$  has preceded any comparable result on either ML II or ML III $\alpha$ / $\beta$  (48), the clinical phenotype of this disorder deserves separate attention. From the few reports with useful clinical information already available, the ML III $\gamma$  phenotype is probably not distinguishable from ML III $\alpha$ / $\beta$ , but as the latter quite distinct from ML II. The age of onset, natural course, and the major sites of morbidity as well as life expectancy appear to be rather congruent to what has been recorded for ML III $\alpha$ / $\beta$ . Remarkably, the majority of observations reported so far concerns families in various parts of the Middle East. Parental consanguinity is noticed in most of these families. Nevertheless, the intrafamilial clinical variability among them may be larger than in ML III $\alpha$ / $\beta$ . Slowly, progressive stiffening of the shoulder joints, of the hands with claw-type deformity, slow growth, and short stature are among the first parental concerns. Intellectual disability is mild or more often absent. Radiographic evidence of mild dysostosis multiplex is initially often overlooked unless osteochondrodystrophy of the hip joints is already present. Some young patients have been observed with “isolated” hip involvement. From adolescence or even earlier, painful hip joints at walking and pain in the lower limbs also when immobile, become the patients' major handicap. Facial coarsening is late and possibly milder than in ML III $\alpha$ / $\beta$ . Thickening of some cardiac valves slowly leading to dysfunction is often recorded and probably consistent in the older patient (48–51).

**103.1.4.2 Histo- and Chemopathology in ML II and ML III $\alpha$ / $\beta$ .** The single most characteristic feature is the presence of large numbers of cytoplasmic, unit-membrane-bound vacuoles abundant in connective tissue cells in skin, gingivae, heart valves, and in the areas of endochondral and membranous bone formation. Because of the many empty-looking vacuoles

**FIGURE 103-3** Manifestations in ML III  $\alpha/\beta$ . (a–d) Patient 1 (female) at 17 years; (e–h) Patient 2 (male) at 9 years. Facial coarsening is mild and gradual in ML III and more apparent in profile, with full cheeks, low nasal bridge and prominent mouth; Stiffness in all large and small joints is slowly progressive, but disabling hip pain from late childhood is the major contributor to morbidity. Contractures of the hips and knees cause the squatting standing posture. Limited range of motion in the shoulders is an early consistent feature. Hand configuration is near normal although soft-tissue hardening and contractures are progressively evident. (Figure reproduced from Cathey, S. S., et al. *J. Med. Genet.* 2010, 47, 38–48, Figure 2, with gratefully acknowledged permission from authors and BJM Publishing Group Ltd, London, UK.)

in the cytoplasm, the swollen cells are called foam cells. Pericytes of capillaries, adventitial cells, and Schwann and perineural cells are similarly affected. In the renal glomeruli, there is foamy transformation mainly in the visceral and barely in the parietal cells of Bowman's capsule. Pathologic changes in neurons and glial cells are minimal, inconsistent, and may be of a secondary nature. Unfortunately, recent postmortem reports are as few in number (52) as the ones in former decades referred to in Reference (1). Histopathology findings are similar in ML II and ML III. In either type of mutant fibroblast strain, the many enlarged cytoplasmic inclusions are filled with pleomorphic material. Contrary to the in vitro observation of I-cells instead of normal fibroblasts in the phase-contrast microscope (Figure 103-4), the in vivo inclusions in mesenchymal cells are either empty or have only sparse granulofibrillar

contents. This paradox also applies to the chemo-pathology data obtained in patient tissues. There is neither histochemical nor biochemical evidence of significant accumulation of lipids, GAGs, glycogen, or lipid- and protein-bound sialic acid in postmortem brain and in visceral organs. In contrast, I-cells accumulate in vitro macro compounds, including GAGs, lipids, and sialylated glycoproteins in addition to free sialic acid. This paradox raises the question of whether the in vitro cultured fibroblasts are unable to achieve the clearance of macromolecular metabolites as they are physically separated from the in vivo neighboring parenchymous tissues. The specific activity of all lysosomal enzymes known to be deficient in I-cells and much increased in the corresponding culture media, are normally active in postmortem liver, spleen, kidney, and also in brain. Only  $\beta$ -D-galactosidase and acid

sialidase have a reduced specific activity in the organs mentioned. The activity of most lysosomal enzymes is much enhanced in the patients' plasma and other body fluids. This finding indicates that at least in connective tissues of the ML patient, the lysosomal hydrolases are unable to reach their intracellular site of function, and enter the ECM and the body fluids. The hyperactivity in plasma is thus an important indication of the diagnosis of either ML II or ML III. That this hyperactivity of plasma lysosomal hydrolases is more pronounced in ML II than in ML III can however not differentiate between the two clinical entities.

The secondarily impaired degradation of glycoproteins is sufficiently extensive in the ML II and ML III patients in order to result in excessive urinary excretion of several SOSs. With  $^1\text{H}$ -NMR spectroscopy-supported analytical technology, the qualitative pattern of the SOSs excreted in ML II or ML III urine samples can be differentiated from that in other oligosaccharidoses (6,7). Methods used in the routine lab for biochemical diagnosis can hardly make such diagnostic distinction. However, the excessive urinary excretion of SOSs continues to have a value of orientation toward the diagnosis. In

**FIGURE 103-4** Living inclusion (I)-cell type fibroblast observed in culture by phase-contrast microscopy (original magnification:  $\times 1000$ ). All cells in fibroblast strains derived from ML II or ML III skin biopsy specimens have a similar in vitro appearance with a juxtanuclear zone that encloses the ER and Golgi apparatus, free of dense granular inclusions. In cultures from obligate heterozygotes, clusters of “I-cells” are found among the normal-appearing fibroblasts (1). (Figure reproduced from Leroy, J. G. (2007) *Oligosaccharidoses, Disorders Allied to the Oligosaccharidoses*, Chapter 108, pp. 2413–2448, Figure 108-2, with gratefully acknowledged permission from the Publisher, Churchill Livingstone, Elsevier, Philadelphia, PA, USA.)

early infancy, interference by the smaller OSs present in any type of milk must be excluded.

**103.1.4.3 From Lysosomal Enzymes to the Primary Metabolic Defect.** Finding the same primary enzyme deficiency in either disorder, albeit less complete in ML III patients, was the formal confirmation that pathogenesis and genetic cause of PHP and I-cell disease are similar and probably allelic. The “I-cell” phenomenon was found to be the consequence of faulty intracellular location and tissue distribution affecting many lysosomal hydrolases and to point to a defect of intracellular trafficking in both disorders. The lysosomal enzymes in plasma affected by the metabolic error and most often used in the laboratory of diagnostic biochemistry in support of the clinical diagnosis include N-acetyl- $\beta$ -D-glucosaminidase (EC 3.2.1.50),  $\beta$ -D-galactosidase (EC 3.2.1.23),  $\beta$ -D-glucuronidase (EC 3.2.31), arylsulfatase A (ASA) (EC 3.1.6.8),  $\alpha$ -D-mannosidase (EC 3.2.1.), and  $\alpha$ -L-fucosidase (EC 3.2.1.51). Other glycoproteins are known to be physically associated with the lysosomal and PM, among them  $\beta$ -D-glucosidase (EC 3.2.1.21) and acid phosphatase (EC 3.1.3.2), are barely if at all affected. Even the more moderately increased activity in plasma of either ML II or ML III obligate heterozygotes, relates to the underlying metabolic defect. The mutant enzymes egress from the cells into the ECM and cannot reenter, contrary to normal mature hydrolases that as phosphoglycoproteins (high-uptake type lysosomal enzymes) easily reenter by pinocytosis into any type of cultured fibroblast, including I-cells. Lysosomal enzymes in I-cells lack a common recognition marker essential for effective intravesicular routing to the lysosomal compartment and for uptake from the ECM. The carbohydrate nature of this recognition marker initially and the functional importance of its phosphate content subsequently were established as of crucial importance. In I-cells, phosphorylation of the oligomannosyl-type glycan in the hydrolases does not occur (ML II) or is much deficient (ML III). Lacking the phosphate-containing recognition marker is the reason that nascent I-cell hydrolases although catalytically active, cannot reach the intracellular lysosomal compartment nor enter cells from the ECM. I-cell lysosomal enzymes isolated from plasma or culture media are so-called low-uptake forms. Recent reviews on the progress in understanding the cause of ML II and ML III contain most references to the original reports (1,38).

Understanding the biosynthesis of the common recognition marker requires knowledge about N-glycosylation of lysosomal hydrolases that are initiated from the moment of their cotranslational insertion into the ER. The glycan precursor is first assembled on a dolicholpyrophosphoryl ER membrane-bound lipid carrier. Mutations that adversely affect the catalysis of any one of these many assembly steps each result in one of the morbid type I congenital N-glycosylation disorders (53). On completion in the ER, the OSs are transferred “en bloc” from the dolichol carrier onto some of the asparagine

(Asn) moieties (glycosylation sites) in the nascent proenzymes. At this stage of completed assembly, the glycan side chains on the immature hydrolases contain no less than 14 monosaccharide residues (Glc3Man9GlcNAc2-Asn). From this point on, the glycoproteins traverse the Golgi cisterns where sequential enzymatic modification takes place along two different pathways. One of the pathways results in N-glycan side chains of the complex type that are not phosphorylated and are unaffected by the ML mutations. The small amounts of normal hydrolases structurally matured along this pathway are either secreted into the ECM or have an incompletely known role within the PM. The larger part of the glycans in precursor enzymes matures along the alternate pathway into oligomannosyl-type OS side chains (Figure 103-5). Phosphorylation occurs as a two-step process in the cis Golgi stacks and involves first the transfer of GlcNAc-1-P to C6 in some of the terminal mannose residues producing initially *N*-acetylglucosamine (GlcNAc)-covered mannose-6-phosphate (M6P). This first step is catalyzed by the UDP-GlcNAc: lysosomal hydrolase GlcNAc-1-phosphotransferase (EC 2.7.8.17) for which the trivial name GlcNAc-1-phosphotransferase (GNPT) is adopted henceforth. This GNPT is completely inactive in ML II and significantly deficient in ML III. The second step that completes the synthesis of the M6P recognition

marker hydrolyzes the blocking GlcNAc and exposes the M6P marker. It is catalyzed by the microsomal, specific glucosidase named GlcNAc-1-phosphodiester  $\alpha$ -*N*-glucosaminidase (EC # 3.1.4.45). It is normal in ML II and in ML III. Mutations affecting this phosphodiester-glucosidase would probably result in either the ML II or ML III phenotype, but have not yet been recorded. This enzyme exerts its activity mainly in the trans-Golgi network (TGN) and it cycles between this TGN compartment and the PM. The uncovering of M6P occurs almost simultaneously with binding of the enzymes to the M6P receptors (MPRs) known to be located in the TGN membranes but also in the intracellular transport vesicles, the prelysosomal organelles, and in the PM. The binding into ligand-receptor complexes ensures the intravesicular transport of hydrolases to the prelysosomal compartment of the cell, where they dissociate due to the acid pH. The ligand hydrolases are delivered to lysosomes, while the MPRs recycle to the TGN membranes and do not enter lysosomes. In patients with I-cell disease or PHP, lysosomal enzymes lack the recognition marker, ligand-receptor complexes are not or barely formed and the segregation into lysosomes is not achieved. Instead in these patients, the abnormal glycoproteins leave the cells and appear in high quantity in body fluids or culture media.

**FIGURE 103-5** Symbolic representation of the most common N-glycans covalently attached to polypeptides at Asparagine (Asn) residues within Asn-X-Ser/Thr sequons, by  $\beta$  N-glycosidic bond. After enzymatic removal of some peripheral mannose residues, the oligomannose type N-glycans (left in figure) are phosphorylated (see Section 103.1.4) in order to acquire the mannose-6-phosphate (M6P) recognition marker of crucial importance for binding of lysosomal enzymes to the M-6-P receptors (MPRs) and ensuring entry into the lysosomal compartment. Unphosphorylated hydrolases lose more mannose residues and are substrates for stepwise synthesis of the complex (middle) and the hybrid type N-glycans (right side of figure). (Figure reproduced from Stanley, P.; Schachter, H.; Taniguchi, N. *N-Glycans* (Chapter 8, Fig 8.1). In *Essentials of Glycobiology*, 2nd ed.; Varki, A., et al, Eds.; CSHL Press: Woodbury, NY, 2009; pp 101–114, with gratefully acknowledged permission by editors and publisher.)

It should be pointed out that both pathways of OSs processing are not as completely distinct as presented above for didactic purposes. Hybrid forms of N-glycans are found on lysosomal hydrolases. However, their binding onto MPRs is considerably less effective than the adequately phosphorylated oligomannosyl-type OSs. Phosphorylation is actually blocking the Golgi-based  $\alpha$ -mannosidases. It has become clear also that the M6P marker has been found also on other glycoproteins that are not targeted to lysosomes. Hence, the M6P structure has other functions as yet incompletely understood (54).

**103.1.4.4 M6P Receptors.** Two distinct M6P receptors (MPRs) have been identified. Once purified, the structural characterization has been helped by cloning the corresponding cDNAs. Both receptors are type I integral membrane glycoproteins composed of an amino-terminal extracytoplasmic domain, a unique transmembrane region, and a cytoplasmic carboxy-terminal domain phosphorylated and palmitoylated at specific sites. One of the MPRs is a large, about 275-kDa protein mainly because of its large extracytoplasmic domain that comprises 15 contiguous repeats of about 147 amino acids each. The repeats have a similar tertiary structure. The other MPR has a molecular size of only 46 kDa and has in its much smaller extracytoplasmic domain. Only a single domain of 159 amino acids is homologous to the repeats in the large receptor. The small MPR requires the presence of cations for optimal ligand binding and is mainly present in its homodimeric conformation. It is called the cation-dependent M6P receptor (CD-MPR). The large receptor, also the most effective one, is the cation-independent receptor (CI-MPR) because it binds M6P marked glycoproteins effectively irrespective of the presence of cations. It adopts the homodimeric form for effective binding of M6P-bearing ligands. The latter occurs more specifically at the repeat segments 3 and 9 in each monomer. The CD-MPR has but one binding site per monomer. Either receptor complements the other one only partially. The absence of both is barely compatible with postnatal survival in MPR knockout mice (38,54,55). There is some specificity to ligand binding onto either MPR. The CI-MPR is a multifunctional molecule. It also binds insulin growth factor II (IGF-II) that does not carry M6P markers. Binding occurs at a single site, repeat N°13 in the monomeric form, and thus different from the anchoring sites for M6P-bearing glycoproteins. It is not clear at present whether or not binding of one type of ligand interferes in any way with the binding efficiency of another. The CI-MPR may have a role in regulating the amount of IGF-II available. Also, retinoic acid is a ligand to the CI-MPR at a site different from both the binding locations of M6P-marked glycoproteins or of IGF-II. One of the less well-defined functions of the large MPR is its role as a liver “tumor suppressor.”

M6P markers are also found on several nonlysosomal proteins, transforming growth factor beta precursor being one among them. The marker is lost from its

mature molecular form, but may target the precursor to the CI-MPR for activation. The function of several other of the M6P-marked proteins remains unknown at present (54).

### 103.1.4.5 Molecular Biology of GlcNAc-1-Phosphotransferase and of Its Genes.

**103.1.4.5.1 ML III $\gamma$ .** An important milestone toward the identification and characterization of the gene(s) encoding the GNPT enzyme has been reached by the successful purification of the bovine GlcNAc-1-phosphotransferase from lactating mammary glands late last century by the group of Canfield in Oklahoma City. The enzyme was found to be an oligoheteromeric protein complex composed of three different polypeptides, each represented in duplicate and represented symbolically as  $\alpha^2\beta^2\gamma^2$ . Original references are available in Reference (1). This result prompted success in identifying the orthologous gene(s) in the human species first with proving that mutations in the *GNPTG* gene (OMIM # 608838), mapped to human chromosome 16p13.3, are the cause of the variant ML IIIC (48), henceforth called ML III $\gamma$  (47), observed in three unrelated families of Druze and Muslim origin. The patients in all three families had consanguineous parents. All were homozygous for a cytosine insertion at nucleotide 500 in exon 7 that causes a shift of the DNA reading frame (FrSh) and the introduction of a premature stop codon (c.500InsC-exon 7→p. 167FrShX91). By the same study, the complete 1219 bp cDNA nucleotide sequence was made available. It predicted a mature protein of 305 amino acids comprising only two glycosylation sites. The gene contains 11 exons and spans about 11.4 kb of genomic DNA. A single 1.2 kb transcript (1221 bp) is detectable in all tissues but the lungs, where a transcript as large as 7.5 kb is found apparently due to alternate splicing and incomplete processing.

Identifying the most probable candidate gene causing the disorder in the families mentioned depended on the results of in vitro complementation studies in heterokaryons formed by pairwise fusion of two different ML III “I-cell” strains. The complementation of either strain resulted in the restoration of the intracellular activity of lysosomal acid hydrolases and of GlcNAc-1-phosphotransferase. Such studies had identified two complementation groups among the ML III patients. One of the groups did not show complementation with ML II-derived cells. The donors were initially called ML IIIA patients. The second group, considered “variant ML III,” was called ML IIIC. Fibroblasts from the latter group were found to be deficient in GNPT activity only when assayed with lysosomal enzymes as phosphate-acceptor natural substrates, but not when the  $\alpha$ -methylmannoside acceptor was used. Complementation group A turned out to be very deficient in GNPT activity irrespective of the type of substrate used. The original reports of results on this subject obtained in the 1970s and 1980s are referred to in the previous edition (1).

In the most recent years, approximately two-dozen different mutations have been characterized in the *GNPTG* gene. The initial impression of a higher prevalence of ML III $\gamma$  in people of Middle East origin is probably due to the inherent ascertainment bias by the first reports (48,49), as most recently Caucasian patients from various European countries have been reported (50,51,56–59). Attempts at comparing the prevalence of ML III $\gamma$  to that of ML III $\alpha/\beta$  are premature at this time. Either disorder is a rare inborn error of metabolism. As parental consanguinity is more often observed in reports on ML III $\gamma$ , it may indeed be the rarer entity of the two. It is of interest that all *GNPTG* mutations so far detected have occurred between the exons 4 and 9 and include among others single nucleotide insertions or deletions and larger molecular deletions, all resulting in the shift of the nucleotide reading frame and in a premature stop signal further downstream. MS mutations and several interesting splice-site mutations have been reported as well. Some of the latter result in exon skipping and/or retaining the introns. Some mutations barely affect the normal level of *GNPTG* mRNA, while others expose the mRNA to nonsense-induced degradation. Details on the ML III clinical syndrome are rarely provided in papers concentrating on the results of *GNPTG* mutation screening. Nevertheless, it is clear that not a single patient with ML II has been described to be associated with a mutant *GNPTG* genotype. Even patients with a so-called intermediate ML syndrome have not been observed. ML III $\gamma$  appears to be a clinically similar, on average probably a somewhat milder disorder than ML III $\alpha/\beta$ . There is a wide clinical spectrum for either. The examples of intra-familial variability in some ML III $\gamma$  families are most striking (49). Contrary to what will be concluded from the *GNPTAB* genotype–phenotype correlation studies (next paragraphs), the phenotypic consequence of any homozygous or compound heterozygous *GNPTG* genotype appears to be of the later onset, milder morbidity type ML III irrespective of mutation nonsense or MS type. This conclusion is in support of the view that the  $\gamma$  subunits in the GlcNAc-1-phosphotransferase protein complex play an incompletely known role, secondary to the catalytic role assigned to the  $\alpha$  and  $\beta$  subunits. One can but wonder whether reports on mutations nearer the 5' or the 3' end of the gene will require adapting the current conclusion about ML III $\gamma$ .

**103.1.4.5.2 ML II and ML III $\alpha/\beta$ : Allelic Disorders.** Both the 5597bp cDNA, the reverse transcribed product of a 6.2kb  $\alpha\beta$  transcript, and the genomic DNA encoding the  $\alpha\beta$  gene were cloned in 2005 by the Canfield group (60) and independently in the same year by Tiede et al. (61). The human gene mapped to chromosome 12q23.3 was shown to contain 21 exons and to span 85kb of gDNA. The prediction that it encodes the precursor of both  $\alpha$  and  $\beta$  subunits in the GlcNAc-1-phosphotransferase protein complex, a protein of 1256 amino acids, was confirmed. Following its translation

into an  $\alpha\beta$  precursor polypeptide of 144kDa with two transmembrane domains, the  $\alpha$  and  $\beta$  subunits are generated by proteolytic cleavage at the lysine 928-asparagine 929 peptide bond. The larger N-terminal  $\alpha$  subunit contains 928 amino acids and the shorter  $\beta$  subunit represents the C-terminal part of the precursor and has 328 amino acids. There are 17 potential N-glycosylation sites in the  $\alpha$  subunit and 3 in the  $\beta$  subunit. In addition to arguments from comparative protein biochemistry, the finding that in vitro transfection experiments with  $\alpha\beta$  precursor cDNA with or without the  $\gamma$ -subunit precursor cDNA resulted in a 17- or 3-fold increased expression of GNPT activity, made it highly likely that the  $\alpha\beta$  precursor cDNA encodes the important catalytic domain of the transferase complex.

Since 2005, the mutant *GNPTAB* genotype in well over 150 patients with either ML II or ML III $\alpha/\beta$  has been reported. All expected types of mutations have been detected by ever more effective mutation screening molecular methodology. They may be subdivided into two groups according to the biological implications. The first group included nonsense (NS) mutations with generation of a stop codon, and microdeletions (del), microinsertions (ins), or duplications (dup) involving a single or only few nucleotides, all resulting in the shift of the nucleotide-reading frame and bringing about a premature stop codon downstream of the mutation site. The members of this mutation group are often called “null” or “amorph” because there is no residual function of the gene products encoded. The second group of mutations comprises MS mutations and the intervening sequence splice-site mutations at or near the intron-exon boundaries. The effect of these mutations is more variable and quite dependent on the precise location and the physicochemical nature or the degree of phylogenetic conservation of the amino acid in question. The effect and the mutations are called “hypomorph” or “leaky” as some residual wild-type function may still be maintained (43,56,59,61–70). In several of the reports cited, the challenging differentiation between MS mutations with morbid effect and the large number of nucleotide polymorphisms has been adequately addressed.

Only occasionally, a larger or more extreme structural alteration of the *GNPTAB* gene has been observed. In five patients in the cohort reported from Japan, the duplication of exon 2 also with frameshift effect has been found in five unrelated patients (68). One structurally aneuploid allele has been explained by the insertion of an ALU sequence, obviously with “null” effect (71). The large structural rearrangement in one allele in a compound heterozygous ML II patient is the sole incompletely resolved defect in the “core” group of the cohort of 61 ML II and ML III $\alpha/\beta$  probands reported by Cathey et al. (43).

Some general conclusions may have already been drawn from the reports on *GNPTAB* mutation screening that represents the major parts of the world. They

confirm that both ML II and ML III $\alpha/\beta$  occur worldwide as rare disorders with a combined prevalence of well below  $15 \times 10^{-6}$  (72) (references in Reference (37)). A most interesting exception is the prevalence of 1/6184 births (carrier rate estimate: 1/39) in the Saguenay–Lac St. Jean region of Quebec. The two-nucleotide deletion 3503\_3504 delTC, known to represent the most frequent mutant *GNPTAB* allele in patients of European descent, is the sole cause in all MLII patients diagnosed in that part of Canada during the last decades. The authors document evidence in support of the founder effect of past centuries and of the population structure with high-distant inbreeding coefficient that explains the extraordinary prevalence figure (67).

In over 95% of either the ML II or the ML III $\alpha/\beta$  patients reported, both *GNPTAB* mutations have been identified. In none of the few bonafide exceptions where no mutation could be revealed, *GNPTG* mutation screening did not find any mutation either. Not a single instance among many dozens of ML II patients has been associated with any *GNPTG* mutant genotype. Hence, ML II $\alpha/\beta$  may be too redundant a term (47) and ML II may remain the more appropriate designation of “I-Cell” disease.

Clearly, the clinically hardly distinguishable entities ML III $\alpha/\beta$  and ML II  $\gamma$  are nonallelic. It is possible, though rather unlikely that the latter would be more prevalent than the former in the countries of the Middle East. More data from everywhere are awaited in order to settle this issue.

Mutation screening is the most effective way to reach formal confirmation of the diagnosis. The abnormal ratio between the specific activity of many lysosomal hydrolases in plasma and cultured fibroblasts does not differentiate ML II from either ML III $\alpha/\beta$  or ML III $\gamma$ , but strongly orients the clinician toward anyone of these disorders. Assay of GNPT requires special laboratory expertise and methods and is not routinely available in the laboratories of clinical biology.

Mutations in the *GNPTAB* gene have been detected in nearly all exons and in many exon-intron borders. The mutation spectra reported from various locations in the world are congruent with only a few exceptions. The mutation c.3503\_3504del CT is by far the most often detected. The frequency reached between 40 and almost 50% of all mutant *GNPTAB* mutant alleles. The report from Japan shows that that country of the Far East the NS c.3565C>T→p.R1184X mutation was found in over 40% of morbid mutant alleles detected in 40 patients. It was found in 8/25 ML II subjects (68). The phenotype of the patients, compound heterozygous with this mutation, depends on the type of the accompanying mutant allele. Its high frequency in Japan may be due to a founder effect. The c.3565C>T NS mutation has been found in much lower frequency in studies representing the countries of the United States, South Korea, Israel, and western Europe respectively (43,64,66).

All results show that the type of *GNPTAB* mutation more than its intragenic location determines the phenotypic implication. This is at variance with the conclusion drawn in the previous section: Neither type of mutation nor intragenic location seems to matter in the *GNPTG* gene. ML III $\gamma$  is the consistent clinical result. However, the intrafamily variability in ML III $\gamma$  remains unexplained.

The large *GNPTAB* genotype–phenotype correlation study by Cathey et al. (43) confirms the consistent findings in previous studies with less clinical details on the cohorts of patients studied (56,57,61,62,64,66,68,70). The rather homogeneous phenotype ML II is directly and strongly correlated with *GNPTAB*-mutant genotypes homozygous or compound heterozygous for two alleles expected to produce no or nearly no *GNPTAB* precursor polypeptide: nonsense and reading frameshift inducing mutations. Premature truncation of either  $\alpha$ - or  $\beta$  subunit in the GBNPT complex is likely to abolish all encoded enzyme activity. Absence or near inactivity of GlcNAc-1-phosphotransferase has been documented in patients with mutant genotypes composed exclusively of “null” or “amorph” mutations (62,64).

The presence of at least one hypomorph allele, MS, or mRNA-splicing mutation, appears to protect against the ML II outcome and consistently results in ML III  $\alpha/\beta$ . The hypomorph allele yields either poorly effective enzyme or insufficient amounts of it and hence much reduced activity (usually between 1 and 10% of normal GNPT) in the ML III $\alpha/\beta$  patients (43,62). Patients with ML III $\alpha/\beta$  associated with two hypomorph *GNPTAB* mutant alleles do not consistently have a milder clinical syndrome than the ones with only a single MS or splice-site mutation in the compound heterozygous genotype. Unfortunately, it is most often in the former type of patient that the clinical onset and the diagnosis may be delayed at least until adolescence. The morbidity, especially the painful hip disease, although sometimes somewhat postponed, becomes equally severe.

The several recent ML studies on large cohorts of patients support the view that the phenotypic spectrum of the GlcNAc-1-phosphotransferase deficiency disorders is at least dichotomous rather than continuously variable (43,56,62,66,68,70). There is still the need for more corroborating data of the contention that the complete lack of GNPT is associated with ML II and some residual activity with ML III $\alpha/\beta$  as the morbid result.

Admittedly, the clinical features in a small minority of ML patients have an intermediate phenotype because they tend to straddle some of the clinical and radiographic criteria set for delineation of the reference ML types, while taking the known variability into account. This small group is likely to be still genetically heterogeneous. In order to discern them, not only the specific mutant genotype but also much detailed information on the clinical features is required (43). The existence

of intermediate phenotypes supports the direct correlation of genotype–phenotype in ML and strengthens the idea of the discontinuous phenotypic spectrum instead of weakening it.

**103.1.4.6 Treatment/Management in ML II and ML III; Animal Models.** Attempts in the last two decades at treating LSDs by allogeneic hematopoietic stem cell transplantation (HSCT) (initially bone marrow transplantation (BMT); more recently cord-blood-derived stem cells) from HL-A compatible donors have met with variable and partial success. Best-known examples of the latter include Fabry disease, Gaucher disease type 1, and Pompe type glycogenosis type 2, and were followed by interesting results in the milder variants of MPS I and MPS VI. Enzyme replacement therapy (ERT) that does not cross the blood–brain barrier, has also brought impressive results to the former group of LSDs, but met with more limited successes in the MPS storage disorders. Few patients with ML II and probably less with ML III $\alpha$ / $\beta$  or ML III $\gamma$  have been subjected to HSCT, still fewer if any to ERT. Even in the few ML II patients who had HSCT in the course of infancy, the treatment known to be challenging to the affected, the hospital staff, and the family, has failed to show any beneficial effect either to the symptoms or the clinical course. The known aspects of the disorder’s pathogenesis most probably preclude any effect by substituting lysosomal hydrolases. Moreover, the likely secondary damage inflicted on the ECM in hard (osteopenia) as well as soft connective tissue (contractures), manifest most early in ML II, and initially less evident but inexorably progressive in the longer-surviving ML III $\alpha$ / $\beta$  or ML III $\gamma$  patients, awaits and requires molecular elucidation before any effective therapeutic approach will become feasible.

Treatment of manifestation issues and medical and routine surgical management are presented in detail elsewhere (37,73). ML II in particular and also the older patients with either ML III $\alpha$ / $\beta$  or ML III $\gamma$  represent serious challenges to the anesthesiologist as both intubations for surgical intervention and detubation are difficult and hazardous. Therefore, any type of surgery should be avoided as much as possible. The airway is smaller and because of mucosal thickening, more marrow than that in age-matched control children. The tracheal wall is stiffer than in normal subjects. Moreover, the swollen mucosae of mouth and pharynx, the enlarged tongue, and the limited extension and flexion in the cervical spine are additional difficulties. Clinical examination of the patient by the anesthesiologist and personal contact with the parents before the procedure is mandatory. The initial diagnosis in some patients with ML II was craniosynostosis and some of them have undergone corrective surgery as treatment. Craniosynostosis is not a feature of ML II.

The osteochondrodystrophy responsible for early growth failure, dysmorphic changes, and much impaired mobility in ML II is milder and more slowly progressive

in ML III. However, in ML III, locomotion becomes increasingly difficult and painful from late childhood because of serious hip disease. Not only joint pain, but also bone pain associated with worsening osteopenia in the progressively more wheelchair-bound ML III adolescent is a consistent complication. Cyclic intravenous (IV) bisphosphonate treatment may reduce the pain and osteopenia caused by excessive bone resorption. This symptomatic treatment has its beneficial effect after a few monthly injection cycles, but must be at least initiated in special treatment centers, where doctors may adequately assess limitations and potential complications of the treatment. The latter is hardly relevant in ML II patients (37,73).

The available animal models are ideally suited to study new therapeutic approaches prospectively. However, until now and in the near future, in vivo and in vitro studies of animal models have been and will be of more immediate importance for improving understanding of the pathogenesis in the mucopolidoses. Heuristic examples with interesting potential include the natural feline ML II model (74) and the knockout mutant mouse models with abolished function of either the *GNPTAB* or the *GNPTG* gene (75,76). The cats with ML II have both clinical picture and course that are congruent to human ML II, including its complications and early, though somewhat variable, timing of fatal outcome. Birth weight in the kittens is within normal limits but growth and weight gain are deficient. The in vitro “I-Cell” phenomenon including both the morphologic and the enzymatic features is congruent to that in human “I-Cell” cultures. Frank blindness is a rare sign in human ML II, except occasionally in the longer-surviving patient. In the absence of signs of decreasing eyesight, the ophthalmologic examination in ML II does not include advanced electrophysiological studies. The affected animals have poor muscle tone as have the affected infants. Progressive ataxia in the cat model has not been reported in the human ML II patient, where it may however help explain that very few children with ML II achieve unaided ambulation. The interesting radiographic features of osteochondrodystrophy should kindle prospective research on the possibly transient skeletal features and hyperparathyroidism in neonatal and young affected kittens. These features were described in the clinical paragraphs of this section (42,44). Proof that the feline model involves indeed the orthologous *GNPTAB* gene has not yet been provided (74).

The “knockout” *gnptab* mouse was obtained by the treatment of mouse embryonic stem (ES) cells with the gene-trapping retroviral vector that had inserted itself in intron 1 of the gene with the effect of truncation of the  $\alpha\beta$  precursor protein behind amino acid 39, out of the normal 1256. The directed gene deletion approach eliminated exons 4–11 of *gnptab* with consequently a much truncated polypeptide from amino acid 59. The ES cell strains were then used to generate mice heterozygous

for the structural ablation of the *gnptab* gene. The latter were inbred in order to generate homozygous offspring.

The specific phenotypic consequences of mice lacking *gnptab* gene function include small size at birth and slower growth rate, severe retinal degeneration with numerous depigmentation spots and attenuated retinal vessels, and markedly hypertrophic tracheal chondrocytes with abundant microvacuoles. Apparently, retinal development is normal in *gnptab*<sup>-/-</sup> mice, but sustaining histology and function of photoreceptor cells is soon deficient. Cytoplasmic inclusions were not seen in fibrocytes and fibroblasts in all tissues examined. However, in secretory cells of several exocrine glands, pancreas and parotid glands among them, tissular disarray and cytoplasmic vacuolization were found in acinar cells. Disrupting the *gnptab* gene completely abolishes phosphorylation of high mannose OSs in acid hydrolases, whereas the knockout of the *gnptg* gene does not affect the size at birth and does not produce animals that have blindness by 5 months of age. Phosphorylation of OSs in lysosomal enzymes is only partial. The  $\alpha$  and  $\beta$  polypeptide subunits in the murine GlcNAc-phosphotransferase enzyme must have adequate power to recognize the lysosomal hydrolases as specific substrates. The  $\gamma$  subunit enhances and/or maintains the transient substrate binding (75–77). Recent reports about in vitro studies of human mutant fibroblasts point at the balance that appears to be held between  $\alpha$  and  $\beta$  subunits on the one and the  $\gamma$  subunit on the other hand. Mutations in either one enhance the presence of the unaffected enzyme component(s) (59,78,79).

Recently, a zebrafish ML II model has been developed by inhibiting *GNPT* expression with translation blocking or splice blocking specific antisense morpholino oligonucleotides. Morphant zebrafish embryos manifest craniofacial defects, impaired motility, abnormal otolith, and pectoral fin development. Altered timing and localization of both type II collagen and Sox9 expression in the craniofacial region of the embryos suggest accelerated chondrocyte differentiation. Excessive accumulation of collagen II is also noticed in the misshaped cartilage tissues. Interpreting the findings and comparison with the slowly progressive features in mammals is hardly possible. The model may point at the protective power exerted by the maternal heterozygous organism during pregnancy against possible adverse effects of human *BNPTAB* mutant genotypes in early stages of embryonic and/or fetal development in mammals (80).

### 103.1.5 $\alpha$ -Mannosidosis

Alpha-Mannosidosis due to deficient lysosomal  $\alpha$ -D-mannosidase (EC 3.2.1.24) among the more slowly evolving oligosaccharidoses has been described first in 1967 by the Swedish physician, Öckerman, in a 4-year-old boy with dysmorphic facial features reminiscent of the ones in Hurler disease, already better-known at

the time. The phenotypic differences among patients, sometimes even within a single sibship, have resulted in controversy about the terminology and the need for delineation of various clinical types within the rather continuously variable spectrum.

$\alpha$ -Mannosidosis is a rare inborn error of metabolism with worldwide prevalence below  $3 \times 10^{-6}$  and with most often a very slowly progressive course and moderately reduced life expectancy. The elevated urinary excretion of mannose-rich OSs and normal excretion of GAGs, only of orientation value to the diagnosis, warrants the disorder's spot among the oligosaccharidoses.

**103.1.5.1 Clinical Phenotype(s).** Controversy about phenotypic delineation relates more to differences in the age of onset and clinical course than to the component symptoms in any fully developed, rather consistent phenotype. Here, the early childhood-onset  $\alpha$ -mannosidosis is termed type I. The clinical course, either short in number of years or quite prolonged, defines the subdivision into types IA and IB, respectively. The late-childhood or adolescent-onset disease is called type II.

The neonatal and infancy period is uneventful in  $\alpha$ -mannosidosis, although a small minority of patients may have congenital equinovarus deformation of the feet and/or may develop hydrocephaly during infancy (81). Instead, neuromotor development is often within normal limits throughout infancy. On average, the milestone of unaided walking is reached with moderate delay. Facial features are coarsening gradually but never reach the severe characteristics known in Hurler disease (MPS IH). The head circumference is large, the forehead prominent, the eyebrows more rounded than normal, and the nasal bridge flattened. Over the years, the enlarging tongue, the wide spacing between the teeth, and some prognathism complete the set of gradually coarsening facial features. The corneae are clear. The delay of speech development, more often than the mildly deficient psychomotor development, is the initial reason for parental concern. Mild hypotonia is a common finding. Joint mobility is only minimally impaired. Fine motor skills remain subnormal and render the patients rather clumsy. Statural growth is most often within normal limits. The clinical description of type IA  $\alpha$ -mannosidosis is thus complete, except for the fact that patients of any subgroup are very prone to respiratory infection and otitis (82). Some immunodeficiency, as yet insufficiently defined, has been documented in  $\alpha$ -mannosidosis (see Section 103.1.5.2). Patients of type IA have been labeled type III in a recent excellent survey (81). Patients grouped here under IB (type II in Reference (81)) may have a less clearly defined, yet early childhood onset. Their overall metabolic syndrome hardly differs from that in subjects belonging to group IA. However, as they do not succumb to the recurrent infections, they run a long clinical course and thus allow the observer to record more late-onset symptoms as is the case of type II patients.

OCD of the skeleton of the dysostosis multiplex type may be mild to moderate. Therefore, it is often not recognized early in the clinical course of the patient without deficiency of statural growth unless clinical kyphoscoliosis prompts the need for radiographic evaluation. The skeletal survey in later childhood shows the thickening of the calvarium, some vertebral dysplasia, narrowing of the basilar parts of the ilia, and slightly widened diaphyses of the short tubular bones in hands and feet (39). Genu valgum deformation, sometimes requiring epiphyseal arthrodesis, is common also in the young  $\alpha$ -mannosidosis patient. Patellar dislocation, often bilateral, is another regularly occurring complication in the knee regions that often requires surgical intervention (83). In either subtype, especially in type IB as well as in the late-onset  $\alpha$ -mannosidosis type II, neurosensory hearing deficit or frank deafness is formally diagnosed although it is not consistently the initial parental complaint except if recurrent bouts of otitis receive professional attention and treatment early in the clinical course (81,84).

Type II  $\alpha$ -mannosidosis has its observable clinical onset beyond the age of 10 years and is often named the clinically mild form. It is called type I in the recent survey earlier referred to in (81).

Intellectual impairment is common to all types of  $\alpha$ -mannosidosis and can be confirmed as soon as psychometric testing becomes feasible. The cognitive deficit is usually mild, only occasionally pronounced. Affected sibs can be much discordant regarding intellectual ability. In all long survivors including the “mild” type II patients, the deficit worsens very slowly over the next decades. Deficient speech remains a consistent and prominent problem as it is resolved only partially by sustained speech therapy. Moreover, declining receptive speech is noticed in the longer survivors. Physical mobility decreases due to persistent or increasing muscle weakness, arthritic and even destructive polyarthropathy (85,86), and the ataxia, apparently associated with generalized cerebral and cerebellar atrophy, features probably not directly related to demyelination (87). In the older patients especially, retinal dystrophy may be shown to be the reason of declining vision (88).

Attention needs to be drawn to the psychiatric signs and symptoms that are significant in a quarter of the adult patients with  $\alpha$ -mannosidosis. Because they are intellectually disabled, recognizing the early stages of this complication is difficult. They can already appear in adolescent patients. The behavioral changes, signs of confusion, depression, and hallucinations tend to occur in episodes of several weeks and are followed by periods of hypersomnia. The psychiatric problems may precede the decline or in some instances the temporary loss of acquired skills (84,89).

The more important differential diagnoses relevant to  $\alpha$ -mannosidosis in the longer surviving patients include CDS and even JNS (see Section 103.1.1), the early onset but long-surviving patients with galactosialidosis (see

Section 103.1.3), ML III $\alpha$ / $\beta$  and ML III $\gamma$  (see Sections 103.1.4.1.2 and 103.1.4.1.3), and obviously the patients with one of the more dysmorphic GAGs storage disorders such as MPS I HS (MIM # 607015) and I S type (MIM # 607016) and also the mild MPS VI (MIM # 253200).

**103.1.5.2 Cyto- and Histopathology.** The vacuolization in peripheral lymphocytes is prominent and more easily demonstrable in  $\alpha$ -mannosidosis than in the other LSDs, but qualitatively not different in the light microscope. In liver tissue, numerous clear vacuoles are seen in hepatocytes and in K  pffer cells. Such cytoplasmic inclusions are found also in bone marrow histiocytes, in endothelial cells of sinusoid vessels, and in lymphocytes in spleen and lymph nodes. The cytoplasm of neurons is distended throughout the CNS. It is packed abundantly with single membrane-bound vacuoles. The latter appear rather clear by EM as they contain but sparsely dispersed reticulogranular material. The severe morphological changes in hepatocytes and in neurons are due to accumulation of abnormal amounts of mannose-rich OSs (see original references in Reference (1)). The accumulation in lysosomes of the specific storage material itself cannot fully explain the pathogenesis of the disorder. Recurrent infection in the first decennium of life contributes significantly to the disorder’s morbidity. Its fatal outcome in childhood is the main point of difference between the clinical Types IA and IB. Decades ago, impaired leukocyte chemotaxis and decreased phagocytosis were documented in a type IA patient. Studying the matter of probable immunodeficiency in  $\alpha$ -mannosidosis is hard, given the paucity of patients and the dependence of subjects at a different age and stage of disorder. In one study of humoral and cellular immunity in six patients, postimmunization levels of antibody were lower in patients than in age- and sex-matched controls. Moreover, a serum factor with phagocytosis-inhibiting effect was detected only in the plasma of the patients (90). Plasma oligosaccharides comprising five and six mannose residues bind to the receptors of interleukin-2 (IL-2) and thus interfere adversely with IL-2-dependent immune responses, such as activation of T-, B-, and NK cells. The blocking of this receptor is probably contributing to the immunodeficiency in patients with  $\alpha$ -mannosidosis (81,90). Autoimmune diseases are apparently more prevalent in mannosidosis patients than in the unaffected population (81,91). In a mouse model, reduction of the degree of N-glycan branching in the complex type glycans induces an autoimmune disorder that resembles human systemic lupus erythematosus (SLE) with the induction of anti-nuclear antibodies (92).

**103.1.5.3 Chemopathology, Enzyme Deficiency, and Diagnosis.**  $\alpha$ -Mannosidosis is an OS because of the excessive urinary excretion of mannose-containing OSs of small molecular size such as Man( $\alpha$ 1 $\rightarrow$ 3)Man( $\beta$ 1 $\rightarrow$ 4)GlcNAc; Man( $\alpha$ 1 $\rightarrow$ 2)Man( $\alpha$ 1 $\rightarrow$ 3)Man( $\beta$ 1 $\rightarrow$ 4)GlcNAc, and Man( $\alpha$ 1 $\rightarrow$ 2)Man( $\alpha$ 1 $\rightarrow$ 2)Man( $\alpha$ 1 $\rightarrow$ 3)Man( $\beta$ 1 $\rightarrow$ 4)

GlcNAc. Other OSs are less abundantly present (see [Figures 103-1 and 103-5](#)). All compounds have GlcNAc at the reducing end (see original references in Reference [\(81\)](#)). These findings are the consequence of the deficient exoglycosidase function of lysosomal  $\alpha$ -D-mannosidase that normally catalyzes the hydrolysis of the mannosidic linkages  $\alpha(1\rightarrow2)$ ,  $\alpha(1\rightarrow3)$  and  $\alpha(1\rightarrow6)$ , present in both the high mannose and the hybrid-type glycan side chains in lysosomal proteins. More refined analytical chemistry of the excreted compounds allows relating the mannose-rich metabolites still more specifically to the metabolic defect at hand [\(6,93\)](#).

The diagnosis of  $\alpha$ -mannosidosis is based on the demonstration in tissues or body fluids of the severe deficiency of lysosomal acid  $\alpha$ -D-mannosidase (LAMAN) with optimal specific activity near pH 4.5. Precautions against  $\alpha$ -mannosidases active at more neutral pH but still interfering with the assay are relevant when artificial enzyme substrates are used. In human plasma, the lysosomal acid enzyme is much less abundant than an “intermediate” also called “neutral” form of  $\alpha$ -D-mannosidase. The former is thermostable and the latter, most active at pH 5.5–6.0, is thermolabile at 56°C. Hence, plasma lysosomal  $\alpha$ -mannosidase can be assayed at its pH optimum of 4.6 most reliably only after thermoinactivation of samples following dialysis against phosphate-buffered saline. In leukocytes or cultured fibroblasts, the enzyme activity is preferably assayed at pH 4.2. Under this condition, the interference by neutral isoenzymes is negligible. Prenatal diagnosis of  $\alpha$ -mannosidosis has been successfully made by showing severe deficiency of acid  $\alpha$ -D-mannosidase activity in cultured amniotic cells or in uncultured chorionic villi (see original references in [\(1\)](#)).

**103.1.5.4 Molecular Biology of  $\alpha$ -D-Mannosidase and Its Gene: Animal Models.** The gene *MAN2B1* (OMIM # [609458](#)) encoding LAMAN (EC 3.2.1.21) has been mapped to chromosome 19 (19pcen-p13.1), spans 21.5 kb of genomic DNA, and is composed of 24 exons. The *MAN2B1* mRNA of about 3.5 kb has slightly different lengths as at least two transcription initiation sites have been identified. Gene expression is ubiquitous, but most prominent in lung, kidney, pancreas, and leukocytes in peripheral blood (see original references in References [\(1,81\)](#)).

LAMAN has been purified and its amino acid sequence completely characterized. The nascent enzyme is synthesized as a single precursor protein. It comprises a 48 amino acid-containing signal peptide at the N-terminal end. On arrival in the lysosomal compartment, the pre-enzyme, a single polypeptide of 962 amino acids (molecular mass: 108.6 kDa), is split enzymatically into three glycopeptides, called A, D, and E, starting from the N-terminal, of sizes 70, 42, and 15 kDa, respectively. The largest among them representing the precursor's N-terminal part, is itself proteolyzed further into three peptides, named A, B, and C, that remain joined by disulfide bridges. The

amino acid sequence of human LAMAN is completely known as it was deduced from PCR-generated cDNA (3030 bp open reading frame) from lung tissue and from cultured fibroblasts. A high degree of similarity has since been confirmed between the human LAMAN amino acid sequence and the orthologous gene product in cattle, cat, and guinea pig. The mature enzyme, in fact a complex of five interacting polypeptides, has undergone extensive molecular folding in the ER, thus rather early in the course of its intravesicular trafficking toward the prelysosomes. Each one of the A, B, and C polypeptides contains one N-glycosylation site occupied by an oligomannosyl-type OS that already has acquired the M6P before leaving the Golgi apparatus. Both the D- and the E-peptide comprise several Asn-glycosylation sites for potential occupation by a complex type of OS.

Over 40 morbid mutations have been reported in the human *MAN2B1* gene, more than half of them being the MS or NS type. At present, nine small deletions and insertions with shift of reading frame as molecular effect have also been detected. Only one large deletion, but no gross rearrangements of the gene have been found. Eight different splice-site mutations are also known [\(94–101\)](#) (consult also earlier original references in References [\(1,81\)](#)).

In disorders with autosomal recessive inheritance, the homozygous or compound heterozygous mutant genotype is expected to be the major determinant of the clinical phenotype rather than the separate effect of either mutant allele. Correlating mutant genotype and resulting  $\alpha$ -mannosidosis phenotype remains challenging for several reasons. Firstly, defining and delineating different phenotypes within a probably continuous clinical spectrum of variation is a difficult assignment, irrespective of the terminology adopted or adhering to. The labels “severe” and “mild” are inadequate, if only the age of onset is taken into account. Clinical complications often determine the patient's fatal outcome. There are few, if any, follow-up reports on patients in adulthood. Secondly, often insufficiently detailed information on the clinical phenotype accompanies reports on causal mutations. Thirdly, the phenotypes in several animal models that continue to be very helpful in understanding pathology and molecular biology aspects show heterogeneous phenotypic expression that is consistently severe in cattle and in cats, and much milder in the guinea pig model. Finally, the clinical difference among affected sibs remains unexplained and may show that environmental and/or genetic factors outside *MAN2B1* mutations also contribute.

The mutations with morbid effect are scattered over the entire *MAN2B1* gene. Except for the MS Arg750Trp (p.R750W) mutation so far most frequently found, most mutations occur in only a few families or are entirely “private.” In homozygous patients, neither the type nor location of the mutations within the gene correlates directly with the clinical phenotype. Even when the amount of residual acid LAMAN activity in leukocytes

or cultured fibroblasts is taken into account, attempts to correlate the severity of the patient's disorder directly with the mutation's location within the linear sequence of the wild-type enzyme fail. However, more recent work supports the conclusion that taking into account the quaternary molecular structure of LAMAN itself, the result of complex molecular folding processes during its transient stay in the ER, is helpful in predicting the residual catalytic function of the mutant enzyme and ultimately the severity of the resulting phenotype especially in homozygous mutant subjects. Comparison of the stereochemical role of the wild-type amino acids to that of the mutant ones encoded by MS mutations in various component peptides identifies mutations that destroy the catalytic site of LAMAN and discerns them from substitutions well outside the active site. The efficacy of the intracellular trafficking of any mutant enzyme is another criterion on which the genotype–phenotype correlation may be built. By various in vitro site-directed mutagenesis experiments, Hansen et al. (97) have introduced 11 MS mutations into human LAMAN cDNA. The wild-type human enzyme synthesized as a 120-kDa precursor was both the target and the reference in these experiments. The resulting mutant proteins were expressed in COS cells (some of them in Chinese hamster ovary cells as well). The enzymes encoded by the mutants p.T355P (exon 8, polypeptide B), p.P356R (ibidem), p.W714R (exon 17, D), p.R750W (exon 18, D), p.L809P (exon 20, D), or by two deletion mutants, respectively, were misfolded, arrested in the ER, and functionally inactive. The LAMANs produced by six other mutations were transported to the prelysosomes and had either less than 5% (H72L; D196E; D196N; R220H) or more than 30% of the normal specific activity: E402K (exon 9, polypeptide B); F320L (bovine exon 3, polypeptide A). Modeling the mutations into the three-dimensional reference structure showed that the mutants with much reduced enzyme activity had substituted amino acids that directly partake in the LAMAN active site as Zn<sup>++</sup>-coordinating amino acids (His72, Asp 196), stabilizing the active-site nucleophile (Arg220) or positioning the active-site residue (Asp319, Phe320) (97). Most MS mutations resulted in misfolding and ER retention. Hence, more amino acids are involved in “wild-type” protein folding in the ER than in direct participation in the catalytic site of LAMAN. Predicting the clinical phenotype is to be more reliable while dealing with genotypes composed of mutations with better biochemical and molecular characterization.

The recent, still more comprehensive homology modeling study of the wild-type and inherited mutations of LAMAN in four species including man, cow, cat, and guinea pig reveals a significant correlation between the mutant genotype and the  $\alpha$ -mannosidosis phenotype (96). The study was based on the premise that the overall protein structure is better preserved during evolution than its linear primary amino acid sequence. This applies

even more to oligomeric proteins, in which ER folding insures that several component peptides contribute one or more amino acids to the enzyme's active site and that several other residues at different sequence locations in the linear precursor protein are determinants of the “wild-type” outcome by the folding process itself. Clearly, homology modeling involves generating three-dimensional structural models of complete mature wild-type bovine LAMAN to serve as a reference model and aligning any target sequence with that in the template or reference structure. Mutations, although scattered over the entire *MAN2B1* gene, seem to be clustered in five mutational hotspots including from the 5' to the 3' end, the following nt sequences: 157–323; 562–679; 961–1204; 1383–1815; and 2124–2746. Each of these regions harbors indeed most of the mutations described in the reports on human  $\alpha$ -mannosidosis in the reports referred to earlier. This approach of comparative collocating the mutations in orthologous positions in different mammals and including the proximity criterion to the enzyme's active site provides better molecular understanding of phenotypic variation and improves predicting the probability of morbid effect in the human species.

**103.1.5.5 Enzyme Therapy; Relevance of Animal Models.** There is still a paucity of well-documented reports on LAMAN treatment, either by allogeneic HSCT or by IV-ERT, in humans with  $\alpha$ -mannosidosis. In particular, more long-term follow-up data about the treatment effects in patients reported previously are required. One report on HSCT applied in four patients with early-onset  $\alpha$ -mannosidosis, in whom slowing neurocognitive development and sensorineural hearing loss had been of major concern, included an evaluation at 1–6 years after the transplant (102). Normalization of leukocyte LAMAN activity, stabilization of cognitive function, and improvement of verbal memory and adaptive skills were the apparent results. The dysostosis multiplex, most often evolving very slowly also in untreated patients, had not worsened since the time of treatment. An objective report on the clinical course of the patients' residual disease after six more years of follow-up would be of great interest.

The feline model of in utero intraperitoneal (IP) transplantation of monocytic cells derived from normal marrow, into fetuses with  $\alpha$ -mannosidosis is potentially valuable not only because it involves a larger animal, but also as a potential way of preventing in utero morbidity before definitive enzyme substitution can be instituted postnatally. The donor monocytic cells engraft and persist for at most 125 days in the recipient's liver, spleen, and even brain, but in numbers below what would be needed in order to halt progression of the inborn error (103). The significant decrease of stored mannose-rich OS in brain is an interesting result. Although termed safe and feasible by the investigators, the need for repetitive IP injections into the fetus render the procedure most

invasive. Follow-up reports on possibly persistent favorable effects are awaited.

The mouse model of  $\alpha$ -mannosidosis has been used several times to study IV ERT and its effects. Following IV administration of LAMAN from bovine kidney, human (h) recombinant (r), or mouse rLAMAN, correction of OS accumulation in affected mice was transient and time as well as tissue and dose dependent. Remarkable but as yet unexplained are the facts in this report that both the human (most effective) and the bovine enzyme (least effective) were barely phosphorylated and that mannose-containing OS in mouse brain was significantly reduced (104). In a more recent study of the IV mouse model, the administration of different doses of hrLAMAN and the clearance of stored OS from visceral tissues was accomplished by low doses, but significant decrease of accumulated OS in the CNS and in peripheral neurons had required much higher doses. Successful transfer of enzyme across the blood–brain barrier was proved by the finding of hrLAMAN in hippocampal neurons. The uptake by the latter cells appears to be independent of the MPRs in the mouse (105).

### 103.1.6 $\beta$ -Mannosidosis

First recognized in goats with a severe affliction of the central as well as the peripheral nervous system and rapidly fetal outcome,  $\beta$ -mannosidosis (OMIM # 248510) was not recognized in humans until 1986 (see original references in Reference (1)). Until the present time, less than two-dozen patients have been reported, unfortunately often at different stages of the disorder's rather severe and often long clinical course. The disease is slowly progressive but with less aggressive morbidity than documented in the caprine species. A disease-free interval in infancy is seen in the majority of patients, but at least one instance of rapidly evolving CNS disease with status epilepticus by 1 year of age and fatal outcome by 15 months is on record. This young victim had angiokeratoma, a symptom more regularly observed in adolescent and adult patients (106–108). Intellectual deficiency often with delayed and poor speech development and also perceptive hearing loss is consistently observed. Recurrent respiratory infections throughout childhood, also before the diagnosis is made, are often reasons for medical attention. Behavioral problems such as hyperactivity, attention deficit in childhood, inappropriate impulsivity, and even aggressive and destructive actions from adolescent age are component features. The clinical diagnostic challenge is enhanced by the fact that physical signs, facial coarsening, and organomegaly are equivocal. Statural growth is not significantly impaired. In some patients, peripheral neuropathy is progressively evident and in others, spinocerebellar ataxia (109), seizures, features of Gilles de la Tourette syndrome, and/or increasing signs of dementia (110) become the sources of growing concern. The neurological features in the  $\beta$ -mannosidosis patient appear often late in the disease course. There are

few if any data on life expectancy. At present, also the age of onset of this rare metabolic disorder is still ill defined, as several of the initial complaints may be too aspecific in order to be interpreted as true, first clinical signs. Follow-up reports on patients already presented to the professional readership are much awaited.

Generalized cerebral atrophy appears to be the hallmark neuroimaging feature in  $\beta$ -mannosidosis patients. The brain stem and cerebellar vermis appear more severely touched by this CNS atrophy (109). Recently, the brain disorder in a patient homozygous for a MS mutation was clinically and neuroradiologically read as a severe leukoencephalopathy (111).

Because routine urinary screening of OS excretion may fail to detect excessive oligosacchariduria, biochemical confirmation of the diagnosis is not an easy assignment. Quantitative assay of the small OSs species, most specifically of the disaccharide Man( $\beta$ 1–4)GlcNAc, is required. Lysosomal  $\beta$ -mannosidase (EC 3.2.1.25) is the exoglycosidase that catalyzes the hydrolysis of the penultimate  $\beta$ -type chemical bond in the glycan N-linked to the glycoprotein (see Figure 103-1). It is specific for the  $\beta$ -mannosidosis activity because all other mannose moieties located more peripherally in the glycan tree have  $\alpha$ -linkages between them.

The clinical diagnosis is confirmed by the demonstration of the completely deficient or significantly decreased specific activity of lysosomal  $\beta$ -mannosidase in either leukocytes or cultured fibroblasts. This enzyme assay is not routinely included in the set of acid hydrolases associated with better-known LSDs.

Molecular studies of the caprine gene *manba* have greatly contributed to the molecular investigation of the human orthologous *MAMBA* gene (OMIM # 609489). It spans 12.9 kb of genomic DNA and has been mapped to 4q22–q25. It is composed of 17 exons separated by rather large introns and is transcribed into a 3293 bp mRNA encoding a single polypeptide of 879 amino acids (see original references in Reference (1)). More than a dozen mutations that are spread over the entire gene, including eight MS and NS, four splicing altering mutations, and two small deletions have been detected in patients and their families (106–114). Finding any meaningful genotype–phenotype correlation between, for example, “null” mutations and severe type of disease must await more clinical detail and follow-up information, more molecular biology–based results, more uniform reporting, and hopefully more worldwide cooperation in studying this rare lysosomal disorder.

In recent years, interesting and relevant molecular biology results have been obtained in mouse models with  $\beta$ -mannosidosis (115,116).

### 103.1.7 Fucosidosis

Originally described as an atypical MPS without urinary excretion of GAGs, fucosidosis is a rare inborn error

of metabolism worldwide. Following the demonstration that the vacuoles in peripheral lymphocytes and Kupffer cells are abnormally swollen lysosomes, Van Hoof and Hers' colorimetric assay of several lysosomal hydrolases with artificial substrates, newly available in the late 1960s, demonstrated the profound deficiency of  $\alpha$ -L-fucosidase in the patient. The label fucosidosis was applied to this disorder. The conclusion of the very low incidence of fucosidosis is supported by the observation of parental consanguinity in more than one-third of the families (1).

**103.1.7.1 Clinical Phenotype.** In probably more than half of the patients, an initial, symptom-free interval of between 6 and 12 months is followed by recurrent upper respiratory infections at the time when a delay in neuro- and psychomotor development also becomes overt. Physical examination at this stage notices slightly coarse facies, thickened lips, and tongue, vaguely reminiscent of the Hurler phenotype, tight skin, and generalized hypotonia with depressed deep tendon reflexes. A sizable proportion of the affected never walk unaided. The initial developmental delay soon alters into decline of neurological skills and severe mental deficiency. Abundant sweating with increased salinity of the sweat has been observed in some of these young patients. Slowing of linear growth becomes apparent before the third birthday. Hepatosplenomegaly, inconsistent in early childhood, is most often absent in older patients. Mild thoracolumbar kyphosis is often confirmed radiographically. Cardiomegaly is initially radiographic rather than a clinical sign. The corneae remain clear. Ophthalmologic examination reveals some tortuosity and caliber irregularity in the retinal vessels. From as early as 3 years of age, the clinical course is compounded by progressive loss of motor skills, hypertonia, and spasticity with hyperreflexia, and sometimes by seizures. Cognitive deficiency progresses inexorably. Patients with this fast-evolving encephalopathy quickly reach the stage of dementia and decerebrate rigidity. They succumb in childhood due to the complications of the CNS disease (117–122). In the past, the disease with this dramatic clinical course had been termed fucosidosis type I.

About half of the patients reported also had severe intellectual handicap with less well-defined clinical onset and almost nonprogressive disease. Angiokeratoma and/or telangiectasias, a dermatological phenomenon indistinguishable from the ones known in patients with Fabry disease (MIM # 301500), were nearly consistent findings in adolescent or adult patients. The observation of this slowly evolving, though clinically severe, disorder had initially prompted the term fucosidosis type II. The longer surviving patients have recurrent, but potentially fatal episodes of dehydration apparently due to the inability to control body temperature (1).

As more clinical reports became available, the contention of two distinct clinical phenotypes could not be upheld. Vascular markings and pinhead-sized skin

lesions similar to angiokeratomata in Fabry disease are not only seen in older patients with slowly evolving disease. Extensive telangiectasia may be present also in the patients with early-onset fucosidosis, particularly in the thenar and hypothenar regions, on the lateral side of the feet as well as in the genital region (119,122,123). Moreover, patients with either type of disease have been observed in a single large pedigree and also among sibs. In somatic cell hybridization experiments with fibroblast cultures derived from either type of fucosidosis, mutual complementation has never been observed. Identical mutant genotypes are detected in patients of either type.

Radiographic skeletal changes are mild in all young patients, but skeletal age lags consistently behind the chronologic age. There is definite dysostosis multiplex in fucosidosis. The mild-to-moderate spondyloepiphyseal dysplasia and the more severe hip dysplasia are usually more pronounced than the diaphyseal widening of long bones (39).

Current magnetic resonance imaging (MRI) illustrates and confirms in vivo the progressive encephalopathy in all patients with fucosidosis as it does in several other hypomyelination disorders, other LSDs among them. In the latter, including fucosidosis, symmetrical, extensive, and confluent signal hyperintensity on T2-weighted images of cerebral periventricular, cerebellar, lobar, and subcortical white matter are consistently found. Following the evaluation of magnetic resonance images by clustering analysis and multivariate testing, Steenweg et al. (124) concluded that T2 hypointensity of the globus pallidus was the most specific and discerning feature in the fucosidosis brain. Signal abnormalities in the basal ganglia and thalamus have been reported in a number of LSDs (125), but only in fucosidosis T2 hypointensity of the globus pallidus has been previously reported (117,120,123).

**103.1.7.2 Histo- and Chemical Pathology.** Weakly periodic acid Schiff (PAS)-positive vacuoles are found in peripheral lymphocytes. By electron microscopy, two types of unit-membrane-bound cytoplasmic vacuoles can be discerned in hepatocytes and Kupffer cells: One type has very light, loosely structured contents; the other is filled with rounded osmiophilic lamellar structures. Also, histiocytes, glomerular endothelium cells, epithelial and other cells in conjunctiva and skin (irrespective of the presence of angiokeratoma), and endothelial cells in bronchial and rectal mucosa are swollen by the presence of similar lysosome-like inclusions. Neuronal and myelin loss in brain is considerable. There are large units, membrane-bound vacuoles in the surviving neurons.

Fucose-containing glycolipids, glycoproteins, and also glycosylceramides accumulate in liver and brain. There is excessive urinary excretion of fucose-containing OS. Thin layer chromatography can distinguish the pattern of OS excretion in fucosidosis from that of other oligosaccharidoses provided the appropriate control samples are simultaneously studied. The consistent biochemical feature

among the many fucosylglycoasparagines, isolated, separated chromatographically, and characterized from urine of patients with fucosidosis, is the disaccharide-containing fucose  $\alpha(1-6)$  linked to GlcNAc (see Figure 103-1). In case of defective or absent  $\alpha$ -L-fucosidase, this bond can barely or not at all be hydrolyzed from the nonreducing end in many types of glycoproteins and glycolipids. One of the glycolipids accumulating in the CNS and in other tissues is the ABO blood group H-antigen, the glycolipid Fuc ( $\alpha 1-2$ )Gal ( $\beta 1-4$ )GlcNAc- $\alpha$ -Gal-ceramide. The implication of fucosidosis on the quantity and quality of the fucosyltransferase(s)-dependent blood group antigens (H, Le<sup>a</sup>, and Le<sup>b</sup>) remains incompletely resolved.

#### 103.1.7.3 Enzyme Defect: Formal Diagnosis.

Assay of  $\alpha$ -L-fucosidase in leukocytes using the fluorescence-generating substrate—4-methylumbelliferyl- $\alpha$ -fucopyranoside—is the routine method for establishing or excluding the diagnosis of fucosidosis (see Figure 103-1). The enzyme deficiency in leukocytes, cultured fibroblasts, amniocytes, or various tissues such as liver, brain, or kidney, is equally profound in patients with the more protracted course as in patients with rapidly advancing disease.

It must be stressed that assaying  $\alpha$ -L-fucosidase in serum or plasma is of no value in the diagnosis of fucosidosis because in about 12% of normal people the average serum or plasma activity is only 5% of that in the rest of the population. In this minority group of normals,  $\alpha$ -L-fucosidase activity in leukocytes is within normal limits.

**103.1.7.4 Molecular Biology of  $\alpha$ -L-Fucosidase and Its Gene, *FUCA1*.** The enzyme has been purified from a variety of tissues. It occurs predominantly in the homotetrameric form but also exists in multiple other combinations of the single, mature 50–60 kDa polypeptide. Glycosylation of the enzyme is important as the size of the nascent monomeric precursor polypeptide is only 51 kDa. In some patients with fucosidosis, the precursor polypeptide remains unprocessed. The gene encoding  $\alpha$ -L-fucosidase has been mapped to chromosome 1p34 and named *FUCA1*. By fluorescence in situ hybridization (FISH), a pseudogene labeled *FUCA1P* has been mapped to 2q31-q32.

*FUCA1* spans 23 kb of genomic DNA and comprises eight exons. The cDNA consists of 2047 bp and includes a 1383 bp open reading frame that encodes a signal peptide of 22 and a mature protein of 439 amino acids. The nucleotide sequence in the pseudogene *FUCA1P* is 80% identical to that in *FUCA1* cDNA, but lacks an open reading frame. By Northern blot analysis, the size of *FUCA1* mRNA was shown to be 2.3 kb in length. This molecular characterization is the prerequisite to detecting a variety of mutations, the spectrum of which has been reviewed in 1999 (126). All mutations, mostly NS, small deletions or insertions, and only a few MS mutations are spread throughout *FUCA1*'s open reading frame. Most of them are encountered in homozygous genotypes, not surprisingly given the high proportion of consanguinity in the families affected. Only the NS Q351X mutation

has been observed in several families. Most of the others are single occurrences and therefore private for the time being. All mutations result in nearly absent enzyme activity and barely detectable cross-reacting material. Apparently, the clinical variability of the disease course is not correlated with either intragenic location or the type of mutations in the mutant *FUCA1* genotypes. Unknown genetic or environmental factors may play a role here. Willems review includes data on genetic polymorphisms within the *FUCA1* gene that explain neither the conclusions regarding the variability of the clinical course nor the variant enzyme activity in human serum (126).

### 103.1.8 Aspartylglucosaminuria

Aspartylglucosaminuria (AGU) (MIM # 208400), an OS with particularly high incidence of 1/18,500 in Finland, is worldwide only occasionally observed. Hence, no wonder that clinical description and delineation, and also metabolic and molecular elucidation have been mainly contributed by Finnish clinicians and scientists.

**103.1.8.1 Clinical Phenotype.** The clinical delineation has been contributed by the original M. Arvio studies (127–130). Umbilical and inguinal herniae and the unusual susceptibility to respiratory tract and ear infections are the most prominent parental concerns and complaints in patients at toddler age or in early childhood. In some, weak suck and general hypotonia could be recorded retrospectively. Infections recur less frequently after the age of 6 years. In 33 cases, the diagnosis was made between the ages of 10 months and 11 years. Intellectual disability, a consistent feature in later childhood, was not established in any patient before the diagnosis of AGU. The milestones of gross motor development are reached at the appropriate age. AGU is not an easy diagnosis before the patient's fifth birthday. Parental concern related most commonly to delay in speech development and short attention span often associated with motor clumsiness and restless behavior that only in a minority of patients was labeled hyperactive, destructive, or violent. The phenotype in early childhood is that of gradually apparent speech and cognitive developmental delay associated with only mildly coarsening facial features. Recently, systematic attention has been paid also to the slowly progressive facial dysmorphism in AGU patients (131). Following the period of slow but still slightly positive neuromotor and mental development in childhood, gradual loss of skills is observed from adolescence and on an average, a more rapid decline of cognition and the ability to interact socially starts after the age of 25 years. Regarding adaptive skills, school-aged patients remain superior, but the middle-aged affected become inferior to individuals with moderately intellectual disability. Behavior problems are encountered in about one-quarter of the adult patients. Seizures and sleep disturbance have been observed and may affect the patients' behavior (132–134). The disorder is slowly progressive and

hence interferes unfavorably with life expectancy (135). Remarkable is the fact that in older patients, apparently true reduction of head size has been carefully documented (136). AGU, clinically a rather homogeneous but rare inborn error, is probably underdiagnosed.

**103.1.8.2 Enzyme Defect: Formal Diagnosis.** This OS is the clinical consequence of the deficiency of aspartyl- $\beta$ -glucosaminidase (AGA) (EC 3.5.1.26), the lysosomal amidase that catalyzes the hydrolysis of the amide bond between asparagine of the N-glycosylation site in glycoproteins and the core GlcNAc residue in any N-linked OS side chain. In the AGU patient, aspartylglucosamine (2-acetamido-1-L- $\beta$ -aspartamido-1,2-dideoxy- $\beta$ -D-glucose) accumulates in tissues and is excessively excreted in the urine (see Figure 103-1). This abnormal metabolite is easily discerned by high-voltage electrophoresis/ninhydrin technology for routine diagnostic purposes (130,137). More sensitive methods for detection of the metabolite in urine and in lymphocytes have been developed.

#### 103.1.8.3 Molecular Biology of Aspartyl- $\beta$ -Glucosaminidase and of AGA, the Gene Encoding It.

The AGA gene has been mapped to 4q32-q33 by deletion mapping and FISH. Isolation and cloning of cDNA were the steps preceding its complete nucleotide sequencing. The human AGA covers 13 kb of genomic DNA and has its open reading frame distributed over nine exons. AGA mRNA is translated as a single pro-precursor polypeptide of 346 amino acids. The N-terminal signal sequence of 23 amino acids is cotranslationally cleaved off in the ER, where major folding of the nascent precursor (49 kDa) and homodimerization occurs. Subsequently, this dimeric complex is autocatalytically activated by proteolysis of the peptide bond between aspartic acid 205 and threonine 206 in each monomer, thus exposing the latter residue for an important role in the enzyme's catalytic site and yielding a tetrameric protein composed of two  $\alpha$  and two  $\beta$  subunits ((138) and references therein). In the Golgi cisterns, glycosylation and the M6P-targeting signal are added for routing of the enzyme to the cell's lysosomal compartment, where still a small reduction in size of the component polypeptides occurs. X-ray crystallographic studies have revealed the three-dimensional structure of the AGA enzyme and the specific roles of the amino acids within the active site (138). This report provides in vitro evidence for the adverse effect of some AGU mutations on the intracellular trafficking of the AGA protein complex. Several steps in the AGA enzyme maturation and macromolecular conformation have been confirmed by studying mutations in AGU patients and even by studies about in vitro mutagenesis. These findings have been extended by Saito et al. (139). At least as effective and useful has been the study of the "founder-type Finnish MS mutation" located in exon 4 that results in the Cys163Ser substitution concomitantly eliminating the all-important disulfide bond with misfolding, failing intracellular routing,

and catalytic deficiency as a result (140,141). The rather complete compilation of AGA mutations up to 2001 (138) and subsequent observations (142) have offered an excellent opportunity to explain in detail the molecular pathogenesis of AGU patients. Most MS mutations that substitute the "wild-type" amino acid for a bulkier one distort the enzyme's macromolecular conformation significantly. Mutations at the dimer interface preclude dimerization in the ER. Active-site mutations not only eliminate catalytic activity but also may adversely affect maturation and hence routing of the precursor protein to the lysosomes.

Mouse models have been studied (137,143,144) and demonstrated the impressive molecular and genomic similarities of the clinical pathogenic effect of mutations in the orthologous *aga* gene in addition to similar cyto- and histopathology. These data are potentially useful for future therapeutic trials. ERT has not been reported in AGU studies. Few results of BMT have led to the conclusion that this type of therapy cannot be recommended in patients after infancy in a disorder that is hard to formally diagnose before the age of 3 years (145). Unfortunately, this conclusion may still stand even following the report of a 5-year follow-up of the apparently stable clinical, biochemical, and neuro-imaging results in two BMT sibs during later childhood (146).

#### 103.1.9 NAGA Deficiency: Schindler Disease and Kanzaki Disease

This severe type of metabolic encephalopathy was first observed in 1989 by Schindler in two German sibs of consanguineous parents. Clinical onset had been in late infancy when the cessation of psychomotor development associated with hyperacusis or exaggerated startle response to noise was noticed. The disorder was soon characterized by deterioration of the CNS function expressed as axial and appendicular hypotonia, grand mal type seizures, poor motor coordination, strabismus, nystagmus, and visual impairment. Joint contractures and the appearance of submucous nodules—the ones in the vocal cords probably explaining the progressive hoarseness—compounded the clinical picture. By 4 years of age, this impressive CNS disorder resulted in severe mental deficit, cortical blindness, rigidity with flexion contractures, myoclonus, and decorticate posturing. In this "vegetative state," the patients had only minimal contact with the immediate environment. Neuropathology studies have shown that Schindler disease is nearly exclusively a disorder of the CNS and the peripheral nervous system without primary involvement of other organ systems (147,148). The clinical course and axonal ultrastructural findings are reminiscent of either Seitelberger-type infantile neuroaxonal dystrophy (MIM # 256600) or of Hallervorden-Spatz disease (MIM # 234200). Some of the patients reported previously with one or the other

neurodegenerative disorder in whom no enzyme studies were performed, may have been examples of Schindler disease.

More recently, two Dutch sibs have been reported: a girl with a neurological disease significantly milder than Schindler disease and the younger brother initially considered to be still presymptomatic because in both the same compound heterozygous mutant genotype was detected (149). Also in 1989, Kanzaki et al. reported on an adult mildly retarded female with disseminated angiokeratoma and glycopeptiduria and with large numbers of vacuoles in skin and kidney cells. The patient had consanguineous parents, but also two unaffected children. Telangiectatic lesions were found also in the conjunctiva, the eye fundus, and the gastric mucosa as endoscopically demonstrated. The disorder in this patient has been called Kanzaki disease (150). Similar patients have since been reported and shown to differ from any other LSD (151).

The abnormal thin-layer chromatographic urinary OS profile pointed to the metabolic nature of the disorder in Schindler's patients. The blood group A trisaccharide, GalNAc- $\alpha$ (1-3)Gal $\alpha$ (2-1)Fuc was a major compound among other glycoconjugates present in excess. All had terminal  $\alpha$ -NAc-galactosaminyl moieties as are found in both the N- and the O-linked glycopeptides, glycoproteins, and glycosphingolipids. Moreover, keratan sulfate had accumulated in various tissue biopsy specimens and in cultured fibroblasts. Therefore, the specific deficiency of lysosomal N-acetyl  $\alpha$ -galactosaminidase (NAGA), predicted in Schindler disease, was confirmed and demonstrated in Kanzaki disease as well. The residual activity was well below 2% of normal in the former and less than 5% of normal in the latter (152). Immunoblotting with monospecific rabbit antihuman enzyme antibody failed to show cross-reacting material in the patients.

The causal mutation in Schindler disease did not interfere neither with the synthesis of the 52 kDa precursor protein, nor with the generation of the mature enzyme (48 kDa) that was however less stable in the German patients than in the Japanese woman.

The *GALB* gene that encodes  $\alpha$ -NAc-Galactosaminidase is located at 22q13. The full-length 2.2 kb cDNA and the complete genomic DNA have been isolated, sequenced, and expressed in COS-1 cells (153,154). The gene has 9 exons and an open reading frame of 1236 bp encoding a 411 amino acid-containing protein. The German sibs were homozygous for the 973G>A transition resulting in the MS mutation that substitutes lysine for glutamic acid (Glu325Lys). In the cDNA of the Kanzaki proband, the 985C>T transition led to the Arg329Trp MS mutation (155). The Chabas Kanzaki-type patients were shown to be homozygous for the NS mutation Glu193X in exon 5. Their disease was apparently due to the complete loss of the NAGA protein (156). The latter authors have shown also that the Dutch siblings were compound heterozygous for the mutant alleles Glu325Lys and Ser160Cys.

All patients reported up to 2001 have been reviewed by Desnick and Schindler (148) and by Bakker et al. (157). The large phenotypic difference between the two types of patients with either Schindler or Kanzaki type of disease, some among them with substitutions in NAGA only three amino acids apart, remains unexplained. Unknown, genetic and/or environmental factors must play a role in the remarkable clinical heterogeneity. That the neuroaxonal dystrophy component may have been coincidental is improbable, but cannot be ruled out as an alternate hypothesis (157).

## 103.2 DISORDERS ALLIED TO OLIGOSACCHARIDOSES

By strictly biochemical criteria, the inborn errors of metabolism to be discussed in this section of the chapter are not oligosaccharidoses. The hereditary disorders associated with excessive urinary excretion and accumulation in tissues of free sialic acid as common hallmark differ pathologically more than clinically from the true oligosaccharidoses (Table 103-2). In one among them, the genetic defect adversely affects the egress of this and other monosaccharides out of the lysosomes; in the other, a rare condition without direct lysosomal involvement, there is constitutive overproduction of free sialic acid. The latter has, contrary to the autosomal recessive mode of inheritance in all other disease entities, been recognized as an autosomal dominant trait. The entities, multiple sulfatase deficiency (MSD) and ML IV were initially included among the mucopolysaccharidoses because the clinical and radiographic phenotypes were considered rather congruent. ML IV has in fact no pathogenetic features connecting it directly with either ML II or ML III $\alpha$ / $\beta$  or even ML I. However, it stresses the role of the transporter proteins in the lysosomal membrane. Mucosulfatidosis has more in common with the GAG storage than with the OSs storage disorders. The causal defect is not lysosomal, but renders the catalytic effect of sulfatases within the lysosomal compartment much deficient. Pyknodysostosis (PKD), a well-known OCD, results from a functionally deficient cathepsin K, a true lysosomal hydrolase. This second part of the chapter closes with the succinct discussion of nodulosis–arthropathyosteolysis (NAO) syndrome, the composite of at least three osteochondrodystrophies originally delineated as separate entities but at present known to be allelic because of a common molecular and biochemical defect.

### 103.2.1 Sialic Acid Storage Disease(s)

**103.2.1.1 Phenotypes Delineated.** Initially, two phenotypes have been discerned that still adequately fulfill the role of clinical reference type. They include (1) infantile free sialic acid storage disease (ISSD) (MIM # 269920) with perinatal or neonatal onset, multisystemic

TABLE 103-2 Disorders Allied to the Oligosaccharidoses

Phenotype		Gene		Enzyme (Protein)

<sup>d</sup>MSD: multiple sulfatase deficiency.

but predominantly CNS morbidity, and fatal outcome before the third year of life; (2) the late infantile-onset type, a slowly progressive brain, and a peripheral nervous system disease with significantly less adverse effect on life expectancy. This type known as Salla disease (MIM # 604369) has a high incidence in the Salla region of northeastern Finland. From the time of delineation, ISSD and Salla disease have been viewed as allelic disorders because of common histopathologic and metabolic findings. Proof of this thesis was provided by the finding of mutations causing either disease in the *SLC17A5* gene (158), which encodes an important lysosomal membrane transporter (159). Not unexpectedly also intermediate phenotypes have been recorded prompting the hypothesis of a continuously variable phenotypic spectrum.

ISSD may present as an obstetric and neonatologic emergency as it figures among the most frequent causes of metabolic non-immune hydrops fetalis. Either disorder represents a diagnostic challenge because screening of urinary excretion of GAGs or OSs yields normal results. Unfortunately, the assay of free sialic acid is too often omitted from the panel of diagnostic tests applied to infants and children with probable LSD.

#### 103.2.1.1.1 Infantile Sialic Acid Storage Disorder.

ISSD, an inborn error of metabolism without ethnic predilection, was first delineated in Finland by Aula et al. in 1979 (160) and subsequently reported from various clinical centers (161) (see more original references in Reference (1)). Ultrasonographic studies during pregnancy have revealed that in a large proportion of cases, disease onset is prenatal and manifests as either frank hydrops fetalis or ascites and/or prominent fetal edema. Concomitantly, intrauterine growth retardation

is recorded (162,163). Premature birth had already been noticed frequently in ISSD (160). In some of these infants, nephrotic syndrome has been formally documented (162,164).

The infant patient is axially hypotonic, has a fair-to-pale complexion, and has an expressionless and sometimes already coarse face. He or she soon presents with often-refractory feeding difficulty and weak cry, and inconsistently with hepatomegaly, cardiomegaly, and/or pericardial effusion. The corneae remain clear, but the retinas are often described as albinoid. Failure to thrive and severe neurodevelopmental delay are soon apparent. At least some facial coarsening with flat nasal bridge and anteverted nostrils becomes consistently evident in later infancy. There is no restriction of motion range in the joints. Inguinal herniae are frequent in males. Neuromental development is minimal. Deep tendon reflexes may become hyperactive. Convulsions are noticed. Recurrent respiratory infections become progressively more threatening and often compounding the failing CNS and other organ functions that cause fatal outcome often around the first birthday.

The radiographic survey finds the skeleton to be osteopenic. There is hip dysplasia, sometimes thoracolumbar kyphosis, and often calcified stippling in soft tissues around the tarsal bones, the hips, or spine, where the vertebrae retain an ovoid configuration. However, the dysostosis multiplex type OCD is usually mild in ISSD (39).

**103.2.1.1.2 Salla Disease.** Patients with Salla disease, first described by Aula et al. in 1979 (165), are normal at birth. The first parental concerns arise by the time the infant reaches the age of 6–12 months. They

relate to slow neuromotor development and generalized hypotonia. Clinical examination confirms the symptoms and may reveal also incipient hyperreflexia and pyramidal spasticity in the legs, truncal ataxia, and nystagmus. Organomegaly is not usually present in patients with Salla disease. The early neuromotor milestones are reached with moderate delay and only about one-third of the patients achieve unaided ambulation. Speech development is more deficient. It has often a dysarthric character and is usually limited to single words. The language acquired in early childhood regresses considerably in subsequent years. Statural growth is only moderately impaired and pubertal development appears to be clinically normal. Facial coarsening is rather mild. At variable ages, tonic/clonic seizures and/or “absence”-like epileptic crises, often refractory to treatment, compound the neurologic syndrome. Interactive non-verbal communication remains remarkably effective whereas motor performance and visually constructive actions and assignments are performed poorly (166,167). The patients may still make some progress in understanding speech and in interacting with the immediate environment (168), while the disorder seems to become more stationary or shows slowing of regression. They are usually sociable and good-humored despite spasticity and athetoid spurious movements. From adolescence, they are often wheelchair-bound and bedridden later on. Motor scales always yield lower results than the mental ones, both being obviously limited. Visual deficiency and retinal changes have not been observed in Salla disease. Motor conduction velocity is slowed and abnormal somatosensory evoked potentials provide indications that also the peripheral nervous system is affected in Salla disease. Average life expectancy is clearly reduced, but patients have been reported who had reached over 60 years of age. Although an inborn error with high incidence in Finland, it has been observed and reported from various places in the world (162,163,169–174) (see also older references in Reference (1)).

The radiographic changes of the skeleton remain mild in Salla disease and at worst approach from a distance, the ones in LSDs with fully expressed dysostosis multiplex (39). MRI type neuroimaging documents hypomyelination of cerebral and cerebellar white matter, already unequivocal in the young patient. Abnormal density changes are found in the basal ganglia. Hypoplasia of the corpus callosum is consistent. Later in the course general cerebral atrophy is manifest due to be further demyelination (175–177).

No wonder that in this predominantly neurologic disorder, only occasional results of more multisystemic examinations are reported. In a Japanese patient, serious renal disease was associated with Salla disease, probably an indication of its allelic nature to ISSD (158). Deficiency of growth hormone and gonadotropins has been detected in an Italian patient (169), a probable indication of damage inflicted on pituitary secretion.

Clearly, colleagues with considerable experience are able to recognize patients with distinctly more severe Salla disease and to correctly predict mutant genotypes, different from the so-called classic Finnish phenotype (168,178,179). See the next section on gene mutation and comments on phenotypic variability in the free sialic acid storage diseases. The phenomenon of intrafamilial clinical variability still remains enigmatic.

**103.2.1.3 Pathology, Biochemical Findings, and Formal Diagnosis.** Peripheral blood smears of patients with either disorder show vacuolization in some of the lymphocytes. Phase-contrast microscopy reveals numerous “empty” cytoplasmic vacuoles in mutant-cultured fibroblasts. Similar vacuolar structures are seen in skin or in conjunctiva biopsy specimens. In parenchymous organs, light and electron microscopy reveal the same abnormalities and demonstrate once more the lysosomal nature of the free SASDs. See older references in Reference (1).

Few reports of classic neuropathology in either ISSD or Salla disease are available in the literature. Postmortem examination of the CNS in two unrelated Salla disease subjects aged over 40 years showed severely reduced white matter and more specifically, marked loss of axons and myelin sheaths accompanied by pronounced astrocytic proliferation. Interesting but probably less specific are the findings of abnormal lipofuscin in cortical nerve cells and neurofibrillar tangles only in neocortical cells and in some basal nuclei (180). An *in vitro* assay that characterized human sialin function (181) revealed that mutant sialin encoded by mutations associated with ISSD completely abolished the transport of sialic acid, whereas the well-known R39C Salla disease-causing mutation slowed down but did not halt the transport. Relevant to the disorders’ pathogenesis are also the results of an astute *in vitro* procedure for structural and functional analysis of transporter molecules of any species using the expression in insect cells (182,183). Glutamate is an excitatory neurotransmitter molecule. The neurotransmitting role of aspartate usually co-stored in synaptic vesicles of hippocampal neurons was controversial because the location and the role of vesicular storage of aspartate were hitherto unknown. The experiments referred to have established that sialin possesses the dual physiological functions of vesicular aspartate/glutamate transporter in addition to its H<sup>+</sup>/sialic acid cotransporter role. Sialin mutations known to be associated with ISSD lose the latter function completely, but partially maintain the former. People with Salla disease lose aspartergic and glutaminergic neurotransmission, but have the sialic acid transport partially preserved. Results recently obtained in the sialin<sup>-/-</sup> mouse model (184) are equally relevant to the pathogenesis of the disorders at hand. These mice are smaller than the control animals, have uncoordinated behavior, and die prematurely. Myelination of the optic nerve, the main site of study, is delayed and deficient in the mutant animals and

the apoptotic death of cells in the oligodendrocytic lineage is enhanced. The authors also found that down-regulation by the heavily sialylated cell-surface adhesion protein (PSA-NCAM), a known myelination inhibitor is concomitantly delayed.

Urinary excretion of free sialic acid is 5–20 times normal in the free SASDs. This initial finding prompted studies of the metabolic turnover of sialic acid and the demonstration that all enzymes catalytically involved in the synthesis or metabolism of sialic acid function normally in these patients. Subsequently, specific intralysosomal retention of sialic acid was recognized and explained by the finding of its negligible rate of egress in patients. In a normal individual this function is dependent on the intralysosomal sialic acid load and correlated with the ambient temperature suggesting a protein-carrier-mediated mode of transport, which also applies to the transport of glucuronide, other acidic monosaccharides, cystine, and apparently also aspartic acid (160,182,185,186). The mean transport rate of sialic acid and glucuronic acid from lysosomal membrane-bound vesicles in obligate heterozygotes was approximately half the average in control cell strains (1,187). Interesting progress has been made regarding the more specific biochemical effects of various *SLC17A5* mutations by the recent studies of Wreden et al. (188). At present, liquid chromatography-tandem mass spectrometry assay, a method not usually available in the routine clinical biochemistry laboratory can quantify free as well as total sialic acids in body fluids including cerebrospinal fluid. This is a major step forward for the diagnosis and even more important for better comprehension of the pathogenesis of the many disorders directly or indirectly related to gene mutations adversely affecting sialic acid metabolism (189).

Prenatal diagnosis of any free SASD must depend on prior identification of the disease-causing mutation in the family. Assay of free sialic acid (SA) in amniotic fluid is an unreliable method for this purpose. Cultured amniocytes (approach not reliable in case of suspected Salla disease) or tissues obtained by CVS can be used for measuring intracellular free SA in the event of suspected ISSD. Demonstration of intralysosomal SA accumulation most reliably provides or excludes the diagnosis (190,191).

**103.2.3.1 The SA Transporter, Sialin: Molecular Biology of Its Gene *SLC17A5*.** The gene causing either free SASD has been mapped to chromosome 6q14–q15 and has been identified, characterized, and sequenced by Verheijen et al. (158). Originally also termed “anionic sugar transporter,” it has been recognized as a member of the SLC17 anion transporter family of phylogenetically related genes and labeled *SLC17A5* (MIM # 604322). It contains 11 exons, all of them coding exons. A cDNA clone of 2.5 kb was shown to contain an open reading frame of 1485 bp, predicting a protein sequence of 495 amino acids.

The protein encoded by *SLC17A5* has been purified, characterized, and termed Sialin (158,192). The amino acid sequence in the SA transporter is extensively analogous to that in other human and mammalian symport proteins, except for the N- and C-terminal regions. Sialin contains no less than 12 transmembrane domains. Northern blot studies revealed the ubiquitous gene expression including the CNS. Various transcripts—the 3.5 kb and 4.5 kb ones being the major ones—have been identified in several human tissues (158,160). The initial RT-PCR analysis of *SLC17A5* cDNA found the homozygous c.115C>T transition resulting in the MS substitution p.R39C in five unrelated Finnish patients with Salla disease. The substitution of the highly conserved arginine by cysteine was confirmed in genomic DNA. This p.R39C MS mutation is a founder mutation in the Finnish population, where the homozygous mutant genotype is present in well over 90% of “classic” Salla disease patients. Verheijen et al. (158) found several different mutations in the *SLC17A5* gene, in either homozygous or compound heterozygous genotypes in different ISSD patients from other countries. Over two dozen pathogenic mutations have meanwhile been identified (163,168,170–173,178,193) and also some apparently nonpathogenic variants of which p.A43T is an example (194).

Some consistency in genotype–phenotype correlations has also become clear: (1) The homozygous MS mutant genotype p.Arg39Cys MS, the single Finnish founder mutation leads to typical Salla disease; (2) the compound heterozygous patients for the p.Arg39Cys and for another *SLC17A5* mutation leads to the more severe, also called intermediate, Salla disease. The same is true for the homozygotes for the p.Lys136Glu MS mutation (195); (3) Compound heterozygosity for other mutations leads invariably to the severe, early-onset type ISSD with more overt multisystemic involvement (194).

## 103.2.2 Sialuria

This inborn error, more interesting from a scientific than from a clinical vantage point, was initially called “French type sialuria” based on the facts that it was first described and biochemically characterized in 1968 by Fontaine et al. in a French patient and that it took almost 20 years before a second patient was reported from New Zealand by Wilcken et al. (see original reference in Reference (1)). The term was created in order to differentiate the disorder from Salla disease that was called “Finnish type Sialuria” at the time. Only the finding of excessive urinary excretion of free SA makes this “disorder” a differential diagnostic challenge for establishing or excluding the diagnosis of a free SASD.

**103.2.2.1 Clinical Aspects.** Drawing a composite picture of the salient features may still be preliminary because of the paucity of patient reports available (165,196,197) and because of the remarkably mild

phenotype. Information on the long-term outcome and prognosis of this inborn error is still lacking.

Five of the six patients observed in different countries and diagnosed in childhood may have been simplex occurrences in the nonconsanguineous families (165,198–200). The mother, a normally functioning homemaker, of the sixth nonconsanguineous patient was also found to be affected (196). This observation supports the autosomal dominant mode of inheritance of sialuria.

The prenatal and neonatal histories of all patients were unremarkable. Birth weights were in the low normal range and so were the infants' length and occipitofrontal circumference, where available. Some of the infants (four males; two females) had mildly coarse facial features. Hypotonia, hepatomegaly, prolonged neonatal jaundice, hypochromic anemia, episodes of diarrhea with threatening dehydration, transient failure to thrive, and hoarseness were inconsistently recorded. In the first 2 years, frequently recurring respiratory infections were compounding the clinical picture. The milestones of neuromotor development were reached with some delay. From the second year of life, facial coarsening and delay in language and cognitive development were additional parental concerns in some instances. Physical growth remained normal in all. General health improved gradually from the second year of life. Except for some mild hypotonia, the neurologic examination did not show any deficiency. In two instances, however a mild seizure disorder persisted, as did mild hepatomegaly in the majority of patients. In all these instances, the disorder appeared to be nonprogressive. Some patients have attended regular-grade school. Others made good progress in special education classes.

The only adult with documented sialuria so far, the mother of one of the probands, had attended regular-grade school classes only unlike all of her unaffected sibs, who had at least successfully completed high school. She is of normal stature and has no facial coarsening but remarkably edematous eyelids. Sialuria has been ruled out in the father and the two older sibs, all also physically and mentally normal. In the proband, urinary excretion of free SA has repeatedly been between 100 and 200 times normal. It was about 80 times normal in the mother (196).

**103.2.2.2 Pathology Studies, Diagnosis, and Molecular Biology.** There is no histologic evidence of lysosomal storage in either peripheral blood lymphocytes or cultured fibroblasts. Abnormalities detected electron microscopically in the mitochondria have been inconsistent and are probably secondary phenomena. Formal diagnosis of sialuria and differentiation from the SASDs is not achieved by the finding of the extraordinary increase of free SA in the patient's urine or its 100-fold excess detectable in sialuria fibroblasts. It must be stressed that expertise is required in selecting the appropriate methodology for the assay of free and total SA (189,197,201,202). The diagnosis may depend

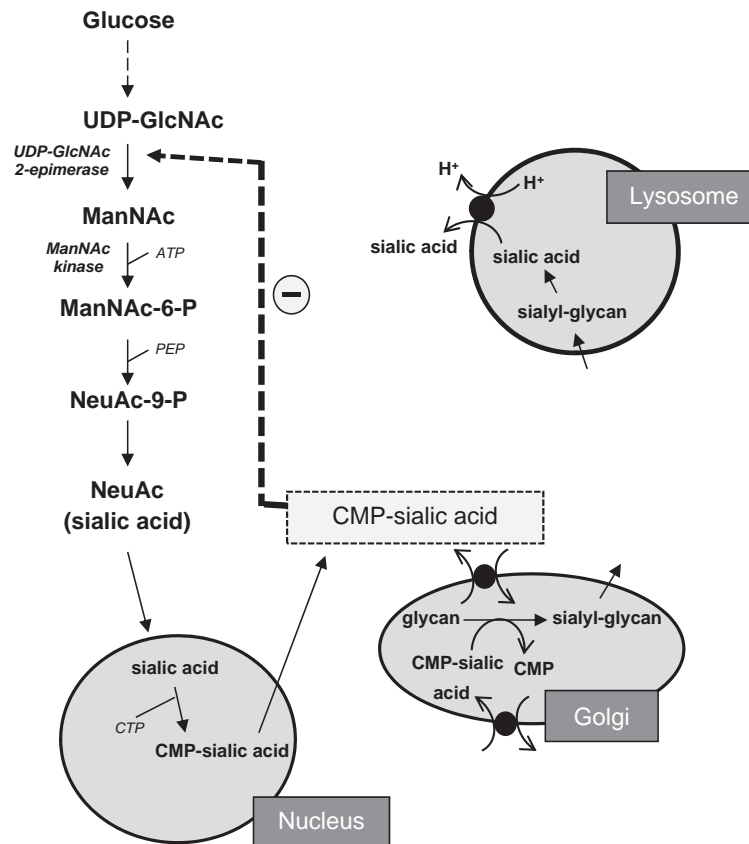

on comparative fibroblast cell fractionation studies: In sialuria, ~90% of free SA is found in the cytosolic cell fraction; that is, 50% in controls and only 10% in SASD fibroblasts, where the storage of free sialic acid is in the lysosomal fraction (165,196) as shown in the previous section.

The assay of the specific activity of the bifunctional enzyme (see further) that catalyzes the first rate-limiting and also the second step in the biosynthesis of SA, yields slightly elevated or near-normal results and is by itself almost irrelevant to the diagnosis of sialuria. Instead of demonstrating a nearly complete lack of feedback inhibition of the first biochemical reaction by CMP-Neu5Ac (CMP-sialic acid), the physiologic end product of SA synthesis, is causally associated with sialuria (Figure 103-6). This lack of allosteric inhibition, a major physiologic control mechanism, causes constitutive overproduction of free SA and was identified as the metabolic defect in sialuria (165,196,197,199). It results in highly excessive production of SA and in very elevated concentrations in the cellular cytoplasm, interstitial tissues, and body fluids such as urine. Based on data obtained by purification and characterization of the rat enzyme, Seppala et al. have cloned and sequenced the human cDNA encoding the corresponding bifunctional enzyme (Figure 103-7) (199).

The gene, termed *GNE*, has been mapped to human 9p13.3. It covers about 100 kb of genomic DNA and consists of 14 exons. Exon 1A is 20 kb upstream from the others all located closely together. Four different splice variants are transcribed from the *GNE* gene. The isoform hGNE is ubiquitously expressed (203). Two of the splice variants encode the hGNE1 protein of 722 amino acids, also called GNE/MNK. The latter symbolic term stands for uridine diphosphate-*N*-acetylglucosamine (UDP-GlcNAc) 2-epimerase (GNE) (EC 5.1.3.14)/*N*-acetylmannosamine(ManNAc) kinase (MNK)(EC 2.7.1.60) (165,199,204). The epimerase domain is in the amino-terminal portion of the protein (amino acids 1–378). The kinase domain is in the carboxy-terminal half (amino acids ~410–722) (Figure 103-7) (199,205).

The allosteric site resides in exon 5 within the epimerase domain. Two observations in sialuria patients are remarkable. First, all sialuria mutations are found in the heterozygous state. This prompts the conclusion that this inborn error is an autosomal dominant trait and confirms the findings in one family pedigree (196). Second, all patients so far reported have one of three MS mutations clustered very closely together: Arg266Trp, Arg266Gln, and Arg263Leu. The short stretch of nucleotides has thus been recognized as the putative allosteric site. Although the boundaries remain undefined, the allosteric site must comprise the codons 263 and 266.

Whether the sialuria in the remaining patients is due to a new mutation or inherited from one of the parents has not been explored. Because of the mild phenotype, sialuria

**FIGURE 103-6** Overproduction of free sialic acid in Sialuria results from failing allosteric inhibition of the rate-limiting, bifunctional GNE (UDPGlcNAc 2-epimerase and manNAc kinase) by CMP-sialic acid that cannot bind to the mutant allosteric site. This is an autosomal dominant trait. CMP-sialic acid is formed in the nucleus by CMP-sialic acid synthase. Its transport to the Golgi apparatus is assisted by a specific Golgi membrane protein. In this location it is a substrate for various sialyltransferases that sialylate complex and hybrid-type glycans among other acceptors. In sialidosis and galactosialidosis (see previous sections in this Chapter) lysosomal catabolism of these macrocompounds is impaired. Free sialic acid leaves lysosomes with the pivotal help of the transporter Sialin that if deficient by mutations blocks or impairs egress with ISSd or Salla disease as clinical result (See previous sections in this Chapter). Also the autosomal recessive hereditary inclusion body myopathy (HIBM) results from mutations in the GNE gene and deficient synthesis of sialic acid. (Figure with minor modifications by M. Huizing, reproduced from Huizing, M.; Krasnewich, D. M. *Hereditary Inclusion Body Myopathy: A Decade of Progress*. Biochim. Biophys. Acta. **2009**, 1792 (9), 881–887, with gratefully acknowledged permission from authors and publisher.)

may not be as rare a disorder as its infrequent reporting makes one assume.

The mutations generating the allosteric metabolic defect are of considerable importance in the study of the physiologic role of free SA and of sialylation in tissues. The metabolic trait is even important for the production of biologic molecules with therapeutic potential and in testing the feasibility of silencing effects by siRNA. Overexpression of GNE in CHO cells containing the allosteric mutation generating p.Arg263Leu resulted in the overproduction of SA and in significant increase of polysialic acid bound to neural cell adhesion molecules (NCAM). Persons with the rather mild entity, sialuria, may be at risk for harmful consequences on the maintenance of cerebral and/or peripheral neurologic functions (206). The GNE sialuria mutation in the model CHO-cell expression system produces recombinant human erythropoietin (EPO), a cytokine for erythrocyte precursors, and expresses homogeneous, highly sialylated EPO of

the desired therapeutic quality instead of the incompletely and heterogeneously sialylated product (207). In vitro silencing of a GNE mutation by synthetic small interfering RNAs in primary sialuria fibroblasts resulted in significantly decreased levels of free SA and thus the restoration of feedback inhibition by CMPneu5Ac (208).

**103.2.2.3 The GNE Gene and Hereditary Inclusion Body Myopathy.** Remarkably the importance of detecting the GNE gene as the cause of the probably mild phenotype sialuria is much enhanced by the finding that mutant genotypes either homozygous or compound heterozygous located anywhere outside the putative allosteric site, cause hereditary inclusion body myopathy (HIBM) (MIM # 600737), first described in 1984 by Argov in Jewish patients of Persian descent. The disorder has its onset in adulthood and is slowly progressive with distal and later also proximal muscular weakness. The lower limbs are more prominently affected, but in many patients the M. Quadriceps is more or less spared. Hence, the

**FIGURE 103-7** Diagram of the GNE protein (derived from GNE transcript isoform 1, also called transcript variant 2) (Ensemble database) (Genbank NM\_005476) with GlcNAc 2-epimerase (left) and manNAc kinase (right) domains. Star points at the location of allosteric site, defined by mutations in either amino acid R363 or R366 in sialuria patients and probably enclosing V364 and M365 as well. The intragenic location of three mutations most commonly causing hereditary inclusion body myopathy in descending order of prevalence include M712T (Persian-Jewish), V572L (Japanese/Asian), and D176V (Japanese) as indicated. (Figure reproduced with gratefully acknowledged permission from designer Dr M Huizing, NIH, Bethesda, MD, USA.)

alternate name of quadriceps sparing myopathy (see earlier references in Reference (1)). Recently, some observations regarding myopathic cardiac involvement in some HIBM patients have been reported (209,210).

Meanwhile, the mutant gene causing HIBM had been mapped to 9p12–p13 and was found to be *GNE* (211,212). The disorder called Nonaka myopathy originally described in Japan (213) has also been etiologically aligned as allelic with HIBM. None of the patients with the myopathy have sialuria. Unlike the heterozygous sialuria patient with a dominant so-called gain-of-function mutation in the allosteric site, patients with HIBM have a haploinsufficiency loss-of-function genotype. In fact, the metabolic effect of the mutations involved is the reduction of GNE-epimerase and/or MNK-kinase specific activity to 30–60% of control values in several in vitro cell types and in cell-free transcription-translation studies (214). As a monomer, GNE/MNK has no catalytic activity and requires di- or even multimerization of the nascent polypeptides in the ER in order to become the mature catalytically active protein. All mutant genotypes wherever located in *GNE* adversely affect the catalytic activity of either protein domain (203). The allelic heterogeneity in HIBM has currently been expanded beyond the 62 different mutations listed in 2009 (204,215). Three among them are found more frequently and appear to be associated with more or less defined ethnic groups: p.Met172Thr is predominantly in patients of Persian-Jewish extraction (216). p.Val572Leu and p.Asp176Val are most often identified in Japanese people (217–219) (see Figure 103-7). It is of interest that NS or frameshift effect mutations with “amorph” or “null” phenotypic consequence represent only one-sixth of the total listed and that homozygotes for mutations with “null” effect have not yet been detected among HIBM patients. Complete absence of GNE/MNK activity is probably lethal as soon observed after the embryonic stage of development in the *Gne* knockout mouse models (204).

Because of its rate-limiting role in the biosynthesis of SA, GNE/MNK is a major determinant of cell-surface glycoconjugate sialylation and a critical regulator of the function of some cell-surface adhesion molecules. Bound SA is widely distributed in normal tissues, in the consistent terminal sugar residue of N-linked complex-type glycan side chains in glycoproteins, and is an important component in gangliosides. However, the expected decrease of intra- and pericellular SA content in HIBM-derived muscle and other tissues has not yet been documented consistently. Hence, the question of an adverse role of hyposialylation of specific glycosylated proteins such as  $\alpha$ -dystroglycan and NCAM in muscle degeneration observed in this myopathy remains unresolved (220–223). Results in mouse models have however indicated that HIBM or Nonaka disease is a potentially treatable entity. In transgenic mice with the Asp176Val mutant genotype and ensuing myopathy, oral administration of ManNAc, an SA metabolite, can prevent and/or postpone muscle weakness and atrophy as well as the histopathologic features usually found in HIBM (224). In another transgenic mouse model (225), oral ManNAc treatment was able to rescue pups homozygous for the Met712Thr variant from the severe glomerular and concomitant proteinuria they had developed instead of signs of myopathy. In the much longer surviving treated mice, sialylation of podocalyxin, the major podocyte sialoprotein, had much increased. Besides the obvious potential as a preclinical treatment in humans, the ManNAc-related results are useful also in the evaluation of hypotheses regarding muscle loss in HIBM and the role of apoptosis (226). Hyposialylation of neprilysin, a metallopeptidase that normally cleaves amyloid- $\beta$ , is known to accumulate in HIBM muscle and promotes muscle degeneration (227). Animal models may be useful in solving questions about the interaction of GNE/MNK with proteins that regulate development (203) and about its probable role in mitochondrial processes (228). The recently published proteomic profile of HIBM has identified more specific

pathways affected by the mutant *GNE* genotype, including most prominent proteins involved in cytoskeleton and sarcomere organization.

Based on the view that adequate sialylation is important at least for maintaining physiologic functioning of several organs, more specifically of muscles, several interesting, careful, and scientific evidence-based efforts at *GNE* gene treatment have been reported. Expression systems have included well-defined in vitro cell strains (229) and the mouse animal model (230). The results have been expertly reviewed by Malicdan (224). It may suffice to point out the significant durable improvement in locoregional muscle function in a human subject #001 with advanced HIBM and without other therapeutic options, who, treated per compassionate investigational new drug, had received four intramuscular injections of wild-type, CMV-driven *GNE* gene plasmid vector encapsulated in cationic liposomes (*GNE* Lipoplex). The local clinical result obtained was in correlation with *GNE* transgene upregulation and local SA induction (231). Transient low-grade fever and pain at the injection site were the sole adverse effects, but proof of principle was obtained for manufacturing “clinical”-grade safe and active “*GNE* Lipoplex” and for opening the road to phase I clinical trials in patients with less-advanced HIBM.

### 103.2.3 MSD (Mucosulfatidosis)

**103.2.3.1 Challenging Clinical Phenotype.** This severe metabolic disorder with an incidence of less than  $1 \times 10^{-6}$  live births in Brazil (232), was first described by Austin in 1965, who subsequently detected the deficiency of several sulfatases, microsomal as well as lysosomal. From the metabolic vantage point, the effects of secondarily affected sulfatases place this disorder among the LSDs. The complete phenotype may be viewed as the composite of features of some of the mucopolysaccharidoses, metachromatic leukodystrophy (MLD) (MIM # 250100) and X-linked ichthyosis (MIM # 308100). The more or less complete phenotype is only observed in the rare patients with true neonatal onset (233) (see earlier references in Reference (1)). Early diagnosis is difficult because in the more “classic” patients with onset in later infancy, only a single or few aspecific symptoms or signs become the first reason of parental concern (232,234–236). They include frequent respiratory infections, hepatomegaly, inguinal herniae in males, microcephaly (233), developmental delay, mildly coarse facial features, limited mobility in hips and knees, broad thumbs and great toes (237), and moderate dysostosis multiplex detected in the radiographic skeletal survey. Even urinary excretion of GAGs and/or sulfatides may not be elevated. The disorder is inexorably progressive. Craniofacial coarsening, a consistent feature in early childhood, is less prominent than in MPS IH (MIM # 607014), but the face in these patients with increasing intellectual disability

becomes expressionless as the patient withdraws from his immediate surroundings. By the third birthday, the metabolic syndrome becomes more completely manifest and the appearance of dermal scaling or frank ichthyosis may point directly at the clinical diagnosis (234). Loss of the few acquired motor skills is unequivocal. The more advanced neurologic picture includes gradual quadriplegia, ataxia, convulsions, nystagmus, and a serious decrease of vision and hearing. The corneae remain clear on clinical inspection. The bedridden MSD patient evolves toward an average fatal outcome in mid-childhood. At present, there is still a need for more detailed clinical reporting, especially in papers that concentrate attention on the causal mutations. Variant phenotypes with truly late childhood onset have been reported (234). MSD in the fetus has been recognized by Steinmann as a rare cause of low urinary estriol during pregnancy (1,236).

**103.2.3.2 Many Sulfatases Affected and Biochemical Diagnosis.** Quantitative assay of GAGs and sulfatides in the patient’s urine may be useful, but in some variant phenotypes unexpectedly useful regarding the orientation toward the diagnosis. Formal confirmation of the diagnosis can be based on demonstrating the concomitant deficiency of several lysosomal sulfatases in peripheral leucocytes or cultured fibroblasts, more particularly of these sulfatases known to be causally related to disorders representing some differential diagnoses under consideration. These lysosomal sulfatases include arylsulfatase A (ASA) or cerebroside sulfatase (EC 3.1.6.8), arylsulfatase B (ASB) or GalNAc-4-sulfate sulfatase (EC 3.1.6.12), L-iduronosulfate sulfatase (EC 3.1.6.13), heparan-N-sulfate sulfatase (EC 3.10.1.1.), GlcNAc-6-sulfate sulfatase (EC 3.1.6.14), and GalNAc-6-sulfate sulfatase (EC 3.1.6.4). These enzymes are known to be specifically deficient in metachromatic leukodystrophy (MLD) (MIM # 250100), Maroteaux–Lamy disease (MPS VI) (MIM # 253200), Hunter disease (MPS II) (MIM # 309900), Sanfilippo A disease (MPS IIIA) (MIM # 252900), Sanfilippo D disease (MPS IIID) (MIM # 252940), and Morquio disease type A (MPS IV) (MIM # 253000), respectively. Assay of the microsomal sulfatase, Arylsulfatase C, using the natural  $3\beta$ -hydroxysteroid sulfate as substrate, an enzyme known to be deficient in X-linked ichthyosis (MIM # 308100) (EC 3.1.6.2), is also recommended as a support of the diagnosis of MSD. A total of 17 sulfatases have been identified in the human genome, 13 of which are already characterized biochemically (238,239).

**103.2.3.3 Deficient Activation of Sulfatases and Primary Genetic Defect.** More than two decades ago, in vitro complementation tests had already ruled out that any gene encoding anyone of the various sulfatases mentioned above would be the cause of MSD. Moreover, in vitro expression of “wild-type” sulfatase cDNAs in MSD-mutant cells have revealed normal synthesis of the various sulfatase polypeptides, but deficient catalytic activity and in some instances decreased stability of these

polypeptides. Expression of the same cDNAs in normal non-MSD cells yields quite active sulfatase components instead. Hence, the sulfatasases require the contribution by the product of a second gene in order to reach normal, full activity. Purified ASA subjected to trypsin digestion yields tryptic peptides separable by reverse-phase high performance liquid chromatography. Amino acid sequencing and determination of molecular mass showed that the peptide containing the amino acids 59–73 had a lower molecular mass than that predicted from the ASA-cDNA nucleotide sequence. Molecular characterization of this peptide revealed the presence at position 69, of 2-amino-3-oxopropanoic acid (C $\alpha$ -formylglycine or FGly) instead of the cysteine predicted for that particular spot. FGly turned out to be the substitute for that specific cysteine in all known eukaryotic sulfatasases. In MSD fibroblasts, the nearly inactive ASA and ASB proteins were shown to have retained the cysteine predicted by the corresponding cDNA codon. Older references to the important results of the independent research groups led by von Figura (Germany) and by Ballabio (Italy) are available in Reference (1).

Chemical modification and activation of nascent sulfatasases by the soluble formylglycine generating enzyme (FGE), also called sulfatase modifying factor 1 (SUMF1) occurs in the ER before their molecular folding and oligomerization. Purification and molecular characterization of SUMF1 have been crucial to the identification of the *SUMF1* gene (MIM # 607939) (240). Cosma et al. have identified this gene independently by microcell-mediated chromosome transfer methodology and in vitro complementation (241). The gene has been mapped to human chromosome 3p26. It spans 101 kb of genomic DNA and has nine exons. Northern blotting detected a 2.1 kb transcript in fibroblasts and in several human organs, thus providing evidence for ubiquitous expression. SUMF1-nascent protein has a molecular mass of 42 kDa. It has 374 amino acids, a number that includes a signal sequence. There is only one glycosylation site in the protein.

The results of several studies have recently shown that *SUMF1* codelivered with arylsulfatase cDNA per adeno-associated virus or lentivirus delivery into cells from patients with one of the several LSDs clearly enhances the sulfatase activity implicated. Moreover, the enhanced effect improved clearance of the intracellular GAG and sulfatide accumulation. Similar results were obtained in vivo in mouse models indicating that this type of combined treatment while providing proof of the sulfatase activating role by SUMF1 may generate beneficial effect in patients (242).

Also, useful data have become available on the intracellular location and trafficking of SUMF1, on its fine regulation, on binding to the sulfatase substrates, and on its more general at least indirect role in metabolism and cellular maintenance.

Although the canonical amino acid ER protein retention sequence KDEL is absent in SUMF1, a substantial

fraction is retained in the ER where it exerts catalytic activation on nascent sulfatasases. A part of the protein is secreted to be taken up by distant cells. To this end, that part of SUMF1 travels to the Golgi, where it is processed into a N-terminally truncated form that appears in the medium apparently for the purpose of endocytosis by other cells (1,243,244). Dynamic interaction with other proteins, such as protein disulfide isomerase (PDI), Erp44, and ERGIC 53, seems to ensure SUMF1's presence in the ER. PDI couples activation and ER retention. With Erp44, the protein is a member of the thioredox protein family and resides in the early secretory pathway. Normal SUMF1 shuttles between the ER and the Golgi as it is protected from proteasomal degradation by their physical association with ERGIC 53. The latter and Erp44 favor SUMF1's export from and retrieval by the ER, respectively (245,246).

All MS mutations encountered so far have affected strictly conserved amino acid residues. Translation of the corresponding mutant mRNAs has not really decreased. Yet, all normal amino acids appear to have a pivotal role in the stability and binding capacity of the "wild-type" protein. Mapping the substituent amino acids to the available crystal structure of "wild-type" SUMF1 (247) showed that they did not directly affect the substrate-binding groove and neither the oxygen-binding pocket nor the catalytic site in the vicinity of the redox-active cysteines. Hence, precise prediction of the pathogenic effect remains difficult. Maintaining the ER location is an important prerequisite for secretion of SUMF1, but clearly not as strict a condition for stability (236,248). Also, the active site in the various sulfatasases is their most evolutionary constrained region making them most probably the likely sole targets of their modifying factors. Gene interaction studies suggest the existence of at least two other cysteine-to-formylglycine converting mechanisms without the involvement of SUMF1 (238). By finding extensive sequence similarity, an SUMF1 paralog protein, called either SUMF2 (249) or pFGE (250), was detected that colocalizes with the active SUMF1 (FGE), has the same tridimensional structure and forms heterodimers with the latter. Obviously, either protein forms homodimers as well. pFGE lacks catalytic activity but can associate with sulfatasases. Overexpression of pFGE (SUMF2) has an inhibitory effect upon the catalysis by the active enzyme. This competitive type of binding to nascent sulfatasases has a fine regulatory effect upon the activation of sulfatasases by SUMF1.

Few if any new reports are available on the neuropathology of MSD in humans. Serial MRI of the CNS in a patient admitted to the hospital at 9 months, showed abnormally high signals in the deep and subcortical white matter. At the time of diagnosis at the age of 29 months, prompted by the appearance of ichthyosis, the patient's neurologic syndrome had much worsened including the earlier recorded MRI findings, in addition to the abnormalities in the peripheral nerves.

Fatal outcome was at the age of 4 years (251). Because of the lack of human data, pathology results in animal models are of special interest. In a mouse model generated with null mutations and complete inactivity of sulfatases, congenital growth retardation, skeletal abnormalities, significant neurologic deficits, and early mortality were recorded. There was progressive cytoplasmic vacuolization and storage of GAGs. In addition, the generalized inflammatory response in the affected animals was much enhanced as indicated by the massive presence of highly vacuolated macrophages near the sites of lysosomal storage. Microglial cells in the cerebellum and the cerebral cortex were activated and accompanied by astroglial and neuronal loss. At the age between 4 and 6 months, a significant increase of inflammatory cytokines and apoptosis marker molecules was found in the CNS and the liver (252). Lysosomal storage impairs autophagosomal delivery of bulk cytosolic content to lysosomes. Mutant mice with diseases corresponding to the human MSD or MPS IIIA had the expected severe neurodegenerative consequences, but showed also the accumulation of autophagosomes apparently because of seriously impaired autophagosome-lysosome fusion. In addition, the massive accumulation of polyubiquitinated proteins and dysfunctional mitochondria and the putative mediators of cell death were demonstrated. Hence the heuristic hypothesis is generated that LSDs are also disorders of autophagy either from the clinical onset or from some time in the later natural course (253).

An interesting effect of the biological role of SUMF1 in some wider metabolic and probably developmental fields of interest is illustrated by the results reported by Buono et al. in the mouse model (254). The concerted activities of the fibroblast growth factor (FGF), Wnt, and Notch pathways are known to balance self-renewal and differentiation processes in hematopoietic stem cells (HSCs). More adequate fine-tuning of the participating protein activities is accomplished by enzyme-mediated remodeling of the large heparan sulfate proteoglycans. SUMF1 activates Sulf 1 (MIM # 610012) (itself probably causally involved in the autosomal dominant mesomelia synostosis (MIM # 600383) in humans (255)) and Sulf2, both being sulfatases that remodel the HSPGs. The authors show that FGF signaling in mice is constitutively activated in *Sumf1*<sup>-/-</sup> HSCs and in hematologic progenitor cells that show upregulation of some specific kinases that promote  $\beta$ -catenin accumulation. This activation by FGF signaling blocks erythroid and B lymphocyte differentiation at specific stages. The animals can be rescued from this adverse effect by blocking the *Sumf1*<sup>-/-</sup> mutation.

The first carefully documented FGE genotype-phenotype correlation study in 10 MSD patients shows that a patient compound heterozygous for two “null” mutations has indeed been born alive, but as expected, had a neonatal onset and early fatal outcome after a short clinical course more severe than the one in four MS mutant homozygotes. Both residual FGE catalytic activity and protein stability

are determining the clinical phenotype but are not consistently predictable in the more classic MSD patients (236).

### 103.2.4 ML IV and Berman Disease

The name mucopolipidosis dates from the time prior to the discovery of the genetic defect, and is a misnomer because the disorder is neither clinically nor pathogenetically directly related to ML I (Sialidosis) or the GlcNAc-1-phosphotransferase deficiency disorders, ML II and ML III, all true oligosaccharidoses. However, the pathogenesis of ML IV being based physically in the membranes of the late endocytic vesicles involved in intracellular trafficking and in the PM, the disorder clearly belongs to the LSDs.

**103.2.4.1 Clinical Phenotype.** ML IV (MIM # 252650) was first observed and described by Berman et al. in 1974. In its classic, unfortunately severe form, the disorder is clinically rather homogeneous and has a high incidence in the Ashkenazi Jewish (AJ) population, but has occasionally occurred in most other ethnic groups. With onset either at birth, infancy, or early childhood, the presenting symptoms include developmental delay, hypotonia that later on may be substituted for some spasticity in the lower limbs, strabismus, corneal opacities, and visual deficit (see further). Unaided walking and effective language are achieved only in a minority of “classic” patients (256). Hand usage is significantly impaired. Growth and physical development are only moderately deficient. The level of social contact and cognition only reach the average expected in a 2-year-old child, and in most instances tend to not change significantly rather than showing signs of further deterioration. This clinical picture remains stable throughout childhood and adolescence and into adulthood. Yet, in some patients, further clinical deterioration may be observed. Since the detection of the genetic defect and the elucidation of some of its clinical effects, it is crucial for the diagnosis that the patient’s constitutive achlorhydria is being documented and that plasma gastrin levels are found to be much elevated. Biopsy specimens of the stomach mucosa consistently show selective vacuolization of the parietal cells. The ML IV patient remains axially hypotonic. There is severely impaired oromotor function and swallowing difficulty (256). The patient may show only brisk tendon reflexes or pyramidal spasticity in the lower limbs. Average life expectancy is decreased as recurrent infections and/or neurological complications represent the most probable dangers to fatal outcome. A few “negatives” need being pointed out: facial coarsening, macrocephaly, and organomegaly are not the features of ML IV.

Radiographically there are no detectable skeletal abnormalities. MRI and MRS of the brain reveal consistently a hypoplastic corpus callosum, demyelination of white matter, and increased ferritin deposited in the basal ganglia including the thalamus as reported by Frei (see

reference in Reference (1)). The degree of prominence of these findings has recently been correlated with the patient's mutant genotype (256–258).

All patients in a series of 22 studied by Smith et al. had some degree of corneal haze (sometimes lesions of erosion), optic nerve pallor, and vascular attenuation and characteristic pigment epithelial changes in the retina. The ophthalmological changes are clearly progressive. In biopsy specimens of the conjunctiva lysosomal histopathology characteristics of ML IV are readily detectable (259).

The number of patients reported with the significantly milder type of ML IV is small. Most examples are encountered in non-Jewish patients in whom growth and physical maturation are normal and neuromotor development only moderately delayed. Easy fatiguing, unsteady gait, and clumsy motor coordination may represent the main clinical complaints. Increased briskness of the deep tendon reflexes is often the only neurological finding. In some patients, a pyramidal encephalopathy is clinically more apparent (256–258). Some patients attend special education classes. However, also here the visual handicap represents the more important threat. With a somewhat more slowly progressive course, all ocular signs that supplement the classic type of ML IV, are detectable also in this variant ML IV (259) (earlier references in Reference (1)).

**103.2.4.2 Relevant Pathology Findings.** Only a few reports on postmortem findings are available (references in References (1,256)). They have shown the presence of histochemically different storage materials in different organs. In conjunctival or skin biopsy specimens, and also in cultured mutant fibroblasts as well as amniocytes, EM study revealed grossly swollen lysosomes with lamellar heterogeneous inclusions. The abnormalities were similar in cell strains derived from either the severe or the variant clinical type of ML IV, and similar also to the heterogeneous storage of gangliosides, phospholipids, and water-soluble macro compounds such as GAGs and glycoproteins, in cell strains from other LSDs with known enzyme defect (260). The in vitro results pointed at a possible defect in the normal function in the membranes of vesicles engaged in endocytotic intracellular trafficking. Meanwhile, mutual complementation tests had supported the conclusion that all ML IV patients have mutations in the same gene.

**103.2.4.3 Molecular and Metabolic Defects.** Genetic linkage studies aiming at mapping the mutation causing ML IV in large Ashkenazy–Jewish families, resulted in locating the causal gene to chromosome 19p13.2–p13.3 and to its cloning and molecular characterization (261–263). The gene termed *MCOLN1* contains 14 exons and spans over 13kb of gDNA. The cDNA sequence has a 1740bp open reading frame predicting an encoded protein of 580 amino acids. Northern blotting in human tissue showed that *MCOLN1* mRNA is ubiquitously expressed in adult and fetal tissues.

It was soon evident that over 95% of AJ patients, all with severe ML IV, have only two mutations in *MCOLN1* considered founder mutations (264) in this ethnic group. The affected are either homozygous for one or compound heterozygous for either. The most frequent mutation, also called the “major” mutation in AJ people, is the 486-2A>C transition in the acceptor site of the third intron. It results in skipping entirely exon 4 in the transcript and the creation of a stop codon further downstream. Premature termination of the translation yields a much truncated and inactive protein. The “minor” mutation, second in frequency among AJ-affected families, is a large genomic deletion of over 6.4 kb. It begins upstream of *MCOLN* and runs as far as into exon 7. It has been designated also as the “c.511del6434” mutation and results in complete loss of the protein encoded by the normal gene. These two “founder” mutations were detected in 73% and 23% of chromosomes in AJ patients (262). Effective and reliable short-cut methodology has been set up in order to screen AJ populations (265,266). Dozens of other *MCOLN1* mutations, most of them in non-AJ patients have been reported (256–258,262,267).

**103.2.4.4 Mucolipins as “Cation Channels” and ML IV Pathogenesis.** The protein encoded by *MCOLN1* called mucolipin 1 shows much structural similarity to proteins in the transient receptor potential (TRP) superfamily of cation channels, mostly Ca<sup>2+</sup> channels. As has been established for this group of proteins, mucolipin1 has six transmembrane domains. Both the N- and the C-terminus reside in the cytoplasm. Therefore, according to convention, mucolipin1 is a multiple pass type III integral membrane protein (molecular model in Reference (256)). A functional stretch of amino acids, located between transmembrane regions 5 and 6 in the TRP cation channel, has been identified as the channel pore domain. The functions of other domains in mucolipin1, at present appropriately called TRP mucolipin 1 (TRPML1), such as a serine lipase domain remain largely unknown (268). In vitro studies of mutant ML IV fibroblasts with documented heterogeneous storage in the lysosomal cell compartment and the accumulation of autophagosomes and fragmented mitochondria indicate that complete and/or partial loss of the several physiologic functions of TRPML1 causes the severe, chronic LSD, ML IV, without the direct involvement of any lysosomal hydrolase. The key question of why the dysfunction of this complex integral membrane protein more specifically causes the impressively serious encephalopathy and ophthalmopathy, is at present receiving its first answers.

The identification of *MCOLN1* soon led to the detection of two closely related genes, both located on chromosome 1 (261). All three encode largely similar integral membrane proteins and are known as TRP mucolipins (TRPMLs) 1, 2, and 3, respectively. TRPML1 is exclusively located in late endosome/lysosome vesicular membranes (269). Its main but not

exclusive function is that of a  $\text{Ca}^{2+}$  channel as shown by electrophysiology studies. It is modulated by intracellular changes in  $\text{Ca}^{2+}$  concentration and by the local low pH. It plays a key role in the biogenesis of lysosomes, a function that is strongly conserved throughout nature (270) (see also references in Reference (268)). Calcium signaling is disturbed in ML IV fibroblasts apparently because TRPML1 channels are unable to release  $\text{Ca}^{2+}$  ions sufficiently with impaired fusion of late endosomes and lysosomes as well-documented consequence (271–273). The TRP channels are required also for efficient fusion of autophagosomes with lysosomes. In addition to the accumulation of autophagosomes, increased amounts and even aggregates of p62 are measured in ML IV cells. This fact suggests abnormal accumulation of ubiquitinated protein inclusions (269). TRPML1 can function also as a  $\text{Fe}^{2+}$  channel. Its failing as such may explain the insufficient plasma  $\text{Fe}^{2+}$  in a sizable minority and the frank microcytic iron deficiency anemia in a smaller proportion of ML IV patients (see Reference (256) and references in Reference (268)). TRPML2 and TRPML3 (mutations in *Trpml3* cause deafness in varitint-waddler mice) both located in the PM and primarily in vesicles along the endocytic pathway, are bound to share functions with TRPML1. Because the three closely related channel-forming proteins form hetero- and homomeric complexes that are crucial regulators of cell viability and of in vitro starvation-induced autophagy (274), all TRPML channel proteins are somehow involved in ML IV's pathogenesis. RNA interference with *MCOLN1* closely mimics the in vitro ML IV phenotype in HEK-293 cells, where chelatable zinc is stored in the accumulated membranous vacuoles. This has been found also in ML IV fibroblasts, but not in controls. The zinc-66 isotope is known to be markedly elevated in brain tissue of TRPML<sup>-/-</sup> mice, not in that of healthy mice. Loss of TRPML1 function also generates dyshomeostasis of intracellular chelatable zinc and is likely to contribute to the ML IV type encephalopathy (275). Also, chaperone-mediated autophagy (CMA) is deficient in ML IV fibroblasts, where the amount of LAMP-2A (lysosome-associated membrane protein 2A) is significantly reduced. TRPML1 may be a docking site for intralysosomal chaperones allowing them to pull substrates for CMA more efficiently (276). As has been noticed also in the previous section on MSD, lysosomal storage itself impairs fusion of autophagosomes with lysosomes (253).

Recent molecular and cell biology studies in cells and animal models representing more than one delineated entity point to the common component of impaired autophagy as of significant importance in the pathogenesis of the clinically most vulnerable CNS phenotype in many of the LSDs. Hopefully improved scientific insight will lead to the design of more rational and effective causal treatment.

### 103.2.5 Pyknodysostosis

As a rare osteosclerotic OCD apparent from early childhood, first described and delineated in 1962 by Maroteaux and Lamy, PKD (MIM # 265800) is characterized by the following physical features: short-limb type, short stature, disproportionally large skull with frontal and occipital bossing, late or never closing fontanelles, rather proptotic eyes, small slightly beaked nose, and receding chin. Often a midline-grooved ridge is present in the palate. Tooth eruption is delayed. A double row of teeth may be present. The enamel is hypoplastic. Early and extensive caries are often noticed. Dental extraction predisposes to recurrent and refractory osteomyelitis of the mandibula that requires skillful surgical intervention. The shortened fingers have a drumstick appearance. Nearly all patients have a history of multiple bone fractures.

At first, the skeletal radiographs reveal only mild and atypical bone density changes that in later childhood become more sclerotic. Many Wormian bones are detectable in the calvarium in addition to open cranial sutures and still wide fontanelles. The mandibular angle is obtuse, the facial bones proportionally small, and the metaphyses of tubular bones undermodeled. The patients have coxa valga. The acromial ends of the clavicles are underossified. Such type defects may also be found in some vertebrae. The terminal phalanges of fingers and toes may also have signs of hypoplasia, but paradoxically in this sclerotic OCD, osteolytic bony lesions as well. Bone density increases with age, but often-radiographic surveys of patients reveal signs of old bone fractures (39). The latter recur frequently in PKD even without or following minor trauma (277–282) (see also earlier references in Reference (1)). Despite the rather unique phenotypic features, the diagnosis has come late in some patients.

Osteoclasts (OCs) that appear normal under light microscopy have an enlarged pericellular zone of demineralization. When studied by EM, these cells contain large, abnormal cytoplasmic vacuoles that contain collagen type I fibrils. Mutant OCs apparently contribute normally to the demineralization process, but do not effectively degrade the organic matrix of bone. The study of bone biopsy specimens (282) from two unrelated PKD patients with severely osteosclerotic skeleton showed multinucleated osteoblasts next to areas of demineralized bone matrix consisting of undigested collagen. Bone trabecular structure was highly disorganized and the decrease of bone remodeling was readily apparent. Apparently normal cathepsin K exerts balancing power over bone turnover. Its deficiency results in profound deterioration of bone quality.

The high proportion of consanguineous families among the PKD probands points to the rarity of the disorder (incidence estimated to be around  $1/75 \times 10^5$ ) and supports the autosomal recessive mode of inheritance. Several families with multiplex patient involvement are

known. The gene has been mapped to 1q21 (references in Reference (283)) characterized subsequently, termed the cathepsin K gene, and labeled *CTSK* (MIM # 601105). It covers 12.12 kb of genomic DNA and contains eight exons, the first one of which is not transcribed. Its expression is most intense in bone (especially osteoclasts: OCs), cartilage, and in skeletal muscle. Human *CTSK* cDNA produces a 1692 b transcript predicting a polypeptide of 329 amino acids (37kDa: molecular mass). The nascent pre-propeptide comprises, as is typical for the cysteine proteinases, a 15-amino acid N-terminal signal peptide, a larger pro-polypeptide with 99 amino acids with a single putative glycosylation site (see earlier references in Reference (1)). The monomeric proenzyme is targeted to the lysosomal compartment via its sole M6P glycan recognition marker and its binding to the MPR receptors (see Section 103.1.4.4). It is surprising that the proenzyme undergoes full maturation and activation only at its target location. The pH-activity profile of cathepsin K, a lysosomal cysteine proteinase most intensely expressed in OCs, is wide with an optimum at pH 6.1. It is a strongly collagenolytic protease with also strong elastase and gelatinase activities. However, the catalytic functions on these important proteins with role mainly in the ECM do not adequately explain the finding of bone sclerotic aspects next to the osteolytic ones in PKD.

Recent work with a the new 129/Sv *ctsk*<sup>-/-</sup> knock-out mouse model that truly imitates the human disorder instead of producing osteopetrosis only has been most revealing in support of explaining both osteolysis and osteopetrosis in the same organism. The findings are most probably relevant for the human PKD as well (284). Mutant *ctsk*<sup>-/-</sup> OCs lacked normal apoptosis and senescence and exhibited both in vivo and in vitro overgrowth. These phenomena were obviously associated with an unusually high number of OCs. The different effects of cathepsin K activity on the skeleton is due to site-specific variation of bone homeostasis, such as osteopetrosis in the tibiae in constant bone turnover during growth on the one hand and osteolysis in calvaria and terminal phalanges, where actual growth comes to a complete halt much earlier. Cathepsin K plays a key role in OC apoptosis and senescence. This work brings the first evidence of the importance of OC senescence in bone homeostasis, of its relevance to the full pathogenic mechanism, and points to the potential as treatment target in PKD (284).

This section ends by referring to the interesting report of promising long-term results in three unrelated PKD patients obtained by a long-term growth hormone treatment program longitudinally monitored by both growth rate measurement and circulating IGF-I assay. All patients have reached near normal stature and skeletal proportions after 12, 6.5, and 5 years, respectively, of personalized treatment. They were homozygous for different *CTSK* MS mutations (285). The treatment

protocol has followed recommendations listed in the consensus statement on diagnosis and the treatment of children with idiopathic short stature (286).

### 103.2.6 NAO Syndrome

The three separately delineated multicentric osteolysis syndromes, Winchester syndrome (MIM # 277950), Torg syndrome (MIM # 259600), and the more recently delineated nodulosis–arthropathy–osteolysis (NAO) syndrome (MIM # 605156) (287,288) have multicentric osteolysis with cutaneous nodule formation and arthropathy as hallmark clinical features. The disorders present in childhood with osteolytic lesions in peripheral parts of the skeleton and nodule formation in the dermal skin layer mainly of the foot soles. The increasing physical disability results from the skeletal changes, but at least as much by progressive contraction and deformity of the small and large joints and by arthralgia. There are some reports of coarsening facial features. In familial consanguineous patients reported from Saudi Arabia with what was called NAO syndrome (MIM # 605156) (287–289), causal involvement of mutations in the matrix metalloproteinase 2 (*MMP2*) gene, located at 16q13, was formally proved. This proteinase, also called gelatinase, is composed of 610 amino acids. Subsequently, also in patients with multicentric osteolysis and with what had been called either Winchester, Torg syndrome, or NAO in several other places in the world, MS, NS, and/or other molecular mutations in the *MMP2* gene (MIM # 120360) were detected (290–297). The NAO syndrome had already deserved a place as Winchester–Torg syndrome in the *Atlas on Bone Dysplasias* by Spranger et al. (39). Detailed radiographic and clinical data on 14 patients in 9 families were offered by Al-Otaibi (298). The NAO syndrome was also presented as differential diagnosis in a large study of familial arthropathy in Saudi Arabian children (289).

The reports on cyclic IV treatment with pamidronate render inconsistent conclusions so far. In seven children with NAO syndrome, aged between 5 and 14 years treated every 3 months during 1 year, conventional radiographs showed increased skeletal mineralization. Bone mineral density in the lumbar spine had increased and the excretion of cross-linked *N*-telopeptide type I collagen had gradually decreased. Limb and joint pain had decreased, but improvement of functional ability was not statistically significant. Also, plasma alkaline phosphatase and osteocalcin levels remained unchanged. The period of treatment was relatively short (299). Phadke et al. (300) have treated two siblings with NAO syndrome for 3 years. There was no clinical improvement although bone mineral density had improved in the axial skeleton. Osteoporosis and osteolysis continued to worsen in the appendicular skeleton.

Clearly, there are several other forms of more or less isolated or syndromic multicentric osteolysis that are not

caused by *MMP2* mutations (301). Discussion of the differential diagnosis falls beyond the scope of this chapter. There is currently an *Mmp2*<sup>-/-</sup> mouse model available enabling effective research on the molecular pathogenesis of NOA (302).

## ACKNOWLEDGMENTS

The author expresses gratitude to the Greenwood Genetic Center, Greenwood, South Carolina, USA, for the overall support, physical accommodation, and stimulating professional environment during a major part of the chapter researching and writing project in the spring of 2011. Special thanks go to Dr Roger E. Stevenson and Dr Tim Wood for the critical reading of the parts or all of the manuscript and for the proposals for text improvement offered.

## Biography

Jules G Leroy MD, PhD, a native and citizen of Belgium, graduated from Ghent University Medical School, Ghent, Belgium, in 1959 and obtained his MS degree in Biochemistry in 1961 from the Ghent University Graduate School.

He trained as a fellow in Pediatrics at Boston Children's Hospital, Harvard Medical School, Boston, Massachusetts, from 1962 till 1964 and in 1968. As a Helen Hay Whitney Foundation fellow, he was a graduate student in Genetics (major) at the Department of Genetics, University of Wisconsin, Madison, Wisconsin, and in Pediatrics (minor) (Department of Pediatrics) (1964–1967). He obtained his PhD degree in Genetics in 1967. Dr Leroy's thesis was on "Studies on the genetics of the Hurler syndrome and related disorders," which contained the discovery and initial delineation of Mucopolidosis II (I-cell disease).

As an associate professor at the University of Antwerp, Belgium (1967–1983), he was the founder and initial director of the Division of Genetics and subsequently promoted to professor and chairman of the Department of Medical Genetics at Antwerp (1973–1983).

Dr Leroy returned to the University of Ghent as professor and chairman of Pediatrics at the University Children's Hospital (1983–1999) and also headed the Department of Medical Genetics between 1984 and 1995.

Obligatory retirement according to Belgian law came in 1999. Since 2000, he has spent periods of four to six months a year as a visiting professor at the Department of Molecular and Human Genetics, Baylor School of Medicine, Houston, Texas (2001–2006). He is still a "visiting senior scholar" during annual periods of two months at the Greenwood Genetic Center, Greenwood, South Carolina. At both locations, he was and is involved in clinical research, teaching, and writing.

Dr Leroy's main professional and scientific interests include inborn errors of metabolism, especially "lysosomal storage disorders"; studies on intellectual disability and pediatric neurology; congenital malformation syndromes and skeletal dysplasias; and studies on genotype–phenotype correlation in monogenic disorders.

Dr Leroy has contributed to well over 200 original publications and review articles in peer reviewed scientific journals or in books.

### GLOSSARY

**Ceramide** – ceramide is the fundamental structural unit common to all sphingolipids. It is a fatty acid chain attached through an amide linkage to sphingosine

**Chaperone therapy** – this therapy consists of enzyme inhibitors at suboptimal concentrations that are able to shuttle the mutant enzymes through the secretory pathway, protecting them from degradation

**Enzyme replacement therapy** – intravenous, intracerebral, or intraventricular delivery of intact recombinant enzyme protein as a form of treatment for a storage disorder due to a mutant enzyme defect

**Glycosphingolipids** – these are ceramides with one or more sugar residues joined in a  $\beta$ -glycosidic linkage at the 1-hydroxyl position

**Sphingolipids** – a class of lipids derived from the aliphatic amino alcohol sphingosine attached to a fatty acid and an R headgroup

**Sphingomyelin** – sphingomyelin has a phosphocholine or phosphoethanolamine molecule with an ester linkage to the 1-hydroxy group of a ceramide

**Substrate reduction therapy** – oral therapy using inhibitors of sphingolipid synthetic enzymes to compensate for the absent-to-low degradative enzyme with the goal of reducing the storage of accumulating sphingolipids in the peripheral and the central nervous systems

### 104.1 INTRODUCTION

Tremendous advances have been made in sphingolipidoses and the various forms of Batten disease over the past

decade. In sphingolipid diseases, of note is the description of the first “loss-of-function” mutation of a key synthetic enzyme for gangliosides, GM3-synthase, in humans (1). We presume that many more defects in synthetic enzymes will be described in the coming years.

A large number of Batten disease genes have been identified, with others on the verge of discovery. Most exciting is the improved understanding of the pathobiology and cell biology of these genetic diseases, which at last is providing real opportunities for therapy. Enzyme replacement therapy (ERT) for Gaucher disease (GD) and Fabry disease (FD) is now a common occurrence. Substrate reduction therapy (SRT) has been approved for Gaucher and may also prove beneficial for the gangliosidoses and FD. Enzyme inhibitors at suboptimal concentrations are able to shuttle the mutant enzymes through the secretory pathway, protecting these enzymes from degradation (chaperone therapy), hence raising residual enzyme activities, and being evaluated for specific gene mutations. Early, presymptomatic bone marrow (BM) replacement is of proven benefit for asymptomatic Krabbe disease and has helped patients with juvenile or later onset forms of metachromatic leukodystrophy (MLD). Rational therapies based on underlying biochemical processes, such as the use of phosphocysteamine (Cystagon®) to overcome the abnormal thio-ester linkage in the infantile form of Batten disease (infantile neuronal ceroid lipofuscinosis (INCL)), are under study. Antiapoptotic therapies such as the drug flupirtine maleate (Katadolon®) are being considered for the treatment of the various forms of Batten disease. Virally mediated gene therapies have given encouraging results in animal models, but much work must be done before use in humans becomes a reality. Stem cell therapies, in spite of the ongoing controversies, are being proposed for use in the late infantile form of Batten disease and other diseases as well. In spite of the positive and hopeful mood of this introduction, let me add that these novel therapeutic interventions are far from perfect and real-life medicine is messy (2). Frequently, children with these diseases are often not ascertained until considerable and non-reversible neurological impairment has occurred. Offering or denying these therapies to families both pose challenging ethical and human problems beyond the scope of this chapter. Avoiding these diseases through genetic screening programs in populations at risk, newborn screening for treatable disorders, and providing genetic counseling and prenatal diagnosis for pregnancies at risk remain the best remedies that we have to lessen the impact of these diseases on families and society.

## 104.2 GM1-GANGLIOSIDOSIS (β-GALACTOSIDOSIS)

### 104.2.1 Introduction

Decreased or absent activity of the lysosomal hydrolase, acid β-galactosidase, can result in one of the two diseases: GM1-gangliosidosis or Morquio disease type B. We discuss GM1-gangliosidosis primarily in this chapter. The

GM1-gangliosidoses are a group of autosomal recessive lysosomal storage diseases, characterized by accumulation of GM1-ganglioside, oligosaccharides, and keratan sulfate (3). Morquio disease, type B, which will be discussed elsewhere, is due to allelic mutations in the acid β-galactosidase gene. Patients have bony disease and corneal clouding, but no involvement of the central nervous system (CNS).

### 104.2.2 Clinical Presentation

There are three clinical types of GM1-gangliosidosis according to the age of disease onset. The classic infantile form (type I) is characterized by onset before 6 months, and death by 2 years of age. This type combines the features of neurolipidosis (neuronal death and macular cherry-red spots) and features of mucopolysaccharidosis (MPS) (hepatosplenomegaly and cardiomegaly, mild dysostosis multiplex). Initial presentation is the failure to thrive and decreased feeding. These children develop gum hypertrophy, macroglossia, corneal clouding, a protuberant abdomen (4), flexion contractures, kyphoscoliosis, frontal bossing, coarse facies, and hypertelorism. Neurologically, these patients are retarded, hypotonic, have an exaggerated startle response to noise, and suffer from generalized seizures. Death ensues at about 2 years due to pneumonia and/or cardiopulmonary failure (Figure 104-1). The juvenile form of GM1-gangliosidosis (type II) presents, usually before the second year of life, as a progressive psychomotor retardation. A triad of ataxia, dystonia, and spasticity of increasing severity develops and death ensues by 20 years of age. They have a lower incidence of organomegaly, skeletal diseases, and cherry-red spots (5). The adult form of GM1-gangliosidosis (type III) is characterized by a later onset during childhood or adolescence with symptoms of dementia, Parkinsonism and dystonia; visceral, macular, and bony involvements are rare. Age at death is variable (6). Few cases of GM1-gangliosidosis presenting with nonimmune hydrops fetalis (NIHF) are reported, with the onset of symptoms as early as 23 weeks of gestation. GM1-gangliosidosis rarely has a prenatal presentation, which usually is fetal or neonatal ascite. Storage

**FIGURE 104-1** Infant with GM1 gangliosidosis and hepatosplenomegaly.

material in Kupffer cells, sinusoidal obstruction and subsequent portal hypertension or hypoproteinemia due to hepatocellular dysfunction, are hypothesized as possible explanations. Other presentations include intrauterine growth restriction (IUGR) and, rarely, pleural effusion and renal tubular dysfunction (7). Severe glycolipid deposition in lymphoreticular organs can induce various complications, as reported in a 5-year-old patient with late infantile GM1-gangliosidosis who developed rare respiratory and intestinal complications. These included common bile duct dilatation due to compression by lymph node swelling of the head of the pancreas and ileus. Adenoidal hypertrophy can lead to obstructive apnea and bronchial compression can result from hilar lymph node swelling (8). More than a dozen cases of extensive dermal melanocytosis in association with GM1-gangliosidosis have been reported. Findings of large, ectopic, and extensive Mongolian spots in newborns may lead to early detection and treatment. Before irreversible organ damage occurs, identification of at-risk families and prevention of complications are needed (9,10).

### 104.2.3 Diagnosis/Testing

Measuring  $\beta$ -galactosidase enzyme activity in leukocytes is diagnostic for affected patients, but is not a good screening method for carriers (11). Quantitative or qPCR assays offer a sensitive, rapid, and reproducible technique for allelic discrimination. These assays lead to rapid diagnosis of gangliosidoses in cats and Shiba dogs and provides a means for large-scale screening for the carrier state, accelerating the eradication of these diseases from feline and canine populations (12,13). This is applicable to humans where there is a prevalence of common alleles. Based on dog studies, amnion and placenta are not useful enzyme sources in GM1-gangliosidosis because of the risk of misdiagnosis as canine placenta contains maternal cells (14). DNA from amniocytes, on the other hand, is a good template for genotyping. Vacuolation of lymphocytes and histiocytes is present as with other lipid storage diseases. Histiocytosis is common in the liver and spleen. Lipid accumulation is noted in BM cells, in neurons, and rectal ganglion cells from rectal biopsies. Radiographs show changes characteristic of dysostosis multiplex. Vertebral deformities are remarkable for hypoplasia and anterior beaking of vertebral bodies in the thoracolumbar region. Bone age is delayed. Computed tomography (CT) and magnetic resonance imaging (MRI) show prominent atrophy, white matter demyelination with or without basal ganglia changes, and enlargement of the ventricular system. There may be increased density of the thalami and reduced intensity of basal ganglia on CT. MRI shows hyperintensity of thalami and basal ganglia on T2-weighted images and hypointensity on T1-weighted sections suggesting a delay in myelination. Cranial imaging findings are quite similar in GM1-gangliosidosis types I and II (15). In the adult form, the putamen may show increased intensity on T2-weighted scans. Accumulation

of GM1-gangliosides in neurons can increase tissue viscosity. This can also sometimes lead to hypointensity of thalami on T2-weighted images (16). A peculiar MRI appearance was recently described in one patient with GM1-gangliosidosis and correlated with postmortem pathology. It consisted of radially oriented stripes of normal signal intensity within diffusely abnormal cerebral white matter. Histopathologic studies confirmed that the stripes represented relative sparing of myelin in the perivenular regions (17).

Proton magnetic resonance spectroscopy (MRS) shows decreased *N*-acetyl aspartate to creatine (NAA/Cr) and increased choline to creatine (Cho/Cr) ratios reflecting relative paucity of axons and neurons, and increased levels of myoinositol, suggestive of gliotic white matter changes (18,19). Cerebral fluorine-18 labeled 2-fluoro-2-deoxyglucose positron emission tomography (PET) shows decreased uptake (20). Electroretinography (ERG) is normal. Visual evoked responses (VERs) peak latencies are delayed. Electroencephalography (EEG) shows nonspecific slowing with epileptogenic foci.

### 104.2.4 Pathology

All patients with GM1-gangliosidosis store GM1-ganglioside in neurons, but only type I patients display coarse facial features, hepatosplenomegaly, prominent skeletal abnormalities (21), and cardiomyopathy. Neuronal cell death and the development of connective tissue and skeletal abnormalities are largely attributable to the intracellular and extracellular storage of galactose-terminal oligosaccharides. There is diffuse brain atrophy in patients with early-onset GM1-gangliosidosis. Neurons are filled with numerous membranous cytoplasmic bodies. As for demyelination, myelin deficit in type I seems to be due to abnormal axoplasmic transport, perhaps consequent to massive neuronal storage of GM1 (22). It also appears that CNS inflammation may play a role in the pathogenesis of GM1- and GM2-gangliosidosis with evidence for microglia/macrophage activation (23). Histiocytes with distended cytoplasm, filled with a fine granular material, are observed in the following organs: liver, spleen, lymph nodes, and thymus (8,24). There is impaired elastic fiber assembly by fibroblasts from type I GM1-gangliosidosis patients, which may explain connective tissue abnormalities (25). Corneal opacities have been described in Shiba dogs with GM1-gangliosidosis and are likely to be the sequel of abnormal accumulation of neutral carbohydrates in the lysosomes of corneal keratocytes. This accumulation induces keratocyte dysfunction and swelling, finally resulting in the irregular arrangement of collagen fibrils in the corneal proper substance (26).

### 104.2.5 Biochemistry

All the three forms of GM1-gangliosidosis are caused by a deficiency in  $\beta$ -galactosidase activity. The latter is a glycoprotein containing 7.5–9% carbohydrate. The terminal

galactose in most sphingolipids is cleaved by  $\beta$ -galactosidase, except for galactosylceramide (GalCer) and galactosyl sphinganine. Acid  $\beta$ -galactosidase is a lysosomal hydrolase that normally removes terminal beta-linked galactose from glycoconjugates, like GM1-ganglioside, generating GM2-ganglioside (Figure 104-2). These patients accumulate GM1, keratan sulfate, asialo-GM1, lyso-GM1, and oligosaccharides in their tissues.  $\beta$ -Galactosidase is also deficient in Morquio disease, type B.  $\beta$ -Galactosidase could be found as a monomer, dimer, and/or in a multiprotein complex with neuraminidase (sialidase) and a protective protein. The protective protein is a glycoprotein that is associated with  $\beta$ -galactosidase and neuraminidase in the lysosome, stabilizing the former and activating the latter (27). Differences in synthesis, posttranslational modification, and degradation of  $\beta$ -galactosidase can give rise to different clinical phenotypes of  $\beta$ -galactosidase deficiency (Morquio syndrome, type B, or GM1-gangliosidosis). GM1-ganglioside is four times higher than normal in the gray matter of diseased patients. Asialo GM1 exceeds normal values by up to 20 times. In type III GM1-gangliosidosis, lipid accumulation is limited to the caudate and putamen. In the liver, only a small amount of GM1-ganglioside accumulates, whereas the levels of keratan sulfate are 50 times higher than what is expected.

One theory about neurodegeneration in GM1-gangliosidosis implicates progressive depletion of iron as demonstrated in mouse brain tissue. Key regulators of iron homeostasis, hepcidin and IL-6, are increased in

gangliosidosis mice. Mouse brain transferrin was reduced, accompanied by a progressive inability of the brain to acquire iron from the circulation. Expression of the transferrin receptor was upregulated reciprocally. Iron administration prolonged survival in the diseased mice by 38%, with delayed disease onset and preserved motor function (28).

Abnormal activation of autophagy accompanied with mitochondrial alterations in a murine model of GM1-gangliosidosis has also been implicated. Modulation of autophagy and restoration of mitochondrial functions may be of therapeutic benefit in this disease (29).

The  $\beta$ -galactosidase gene can give rise to two transcripts: GLB1 and elastin-binding protein (EBP). Also, the accumulation of keratan sulfate in the setting of primary GLB1 mutations or defects can give rise to secondary defects in elastogenesis. Impaired elastogenesis, due to a secondary deficiency of EBP and keratan sulfate storage, was demonstrated in fibroblasts from a juvenile GM1-gangliosidosis patient (30).

### 104.2.6 Genetics

The gene responsible for GM1 gangliosidosis has been identified and is located on chromosome 3p21.33. The mode of inheritance is autosomal recessive. Molecular genetic analysis revealed heterogeneous gene mutations in all clinical forms of GM1-gangliosidosis with no clear genotype–phenotype correlation evident. Neither the

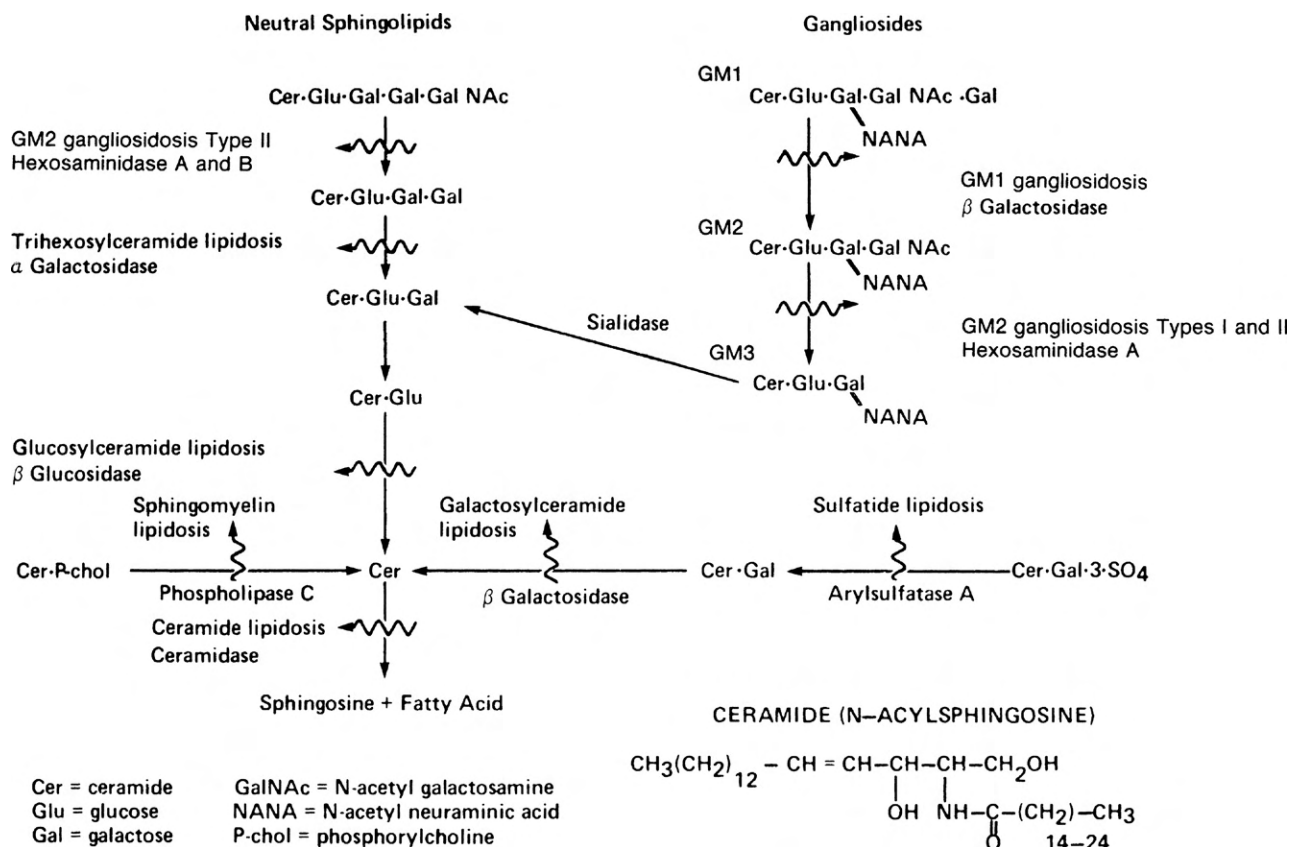

FIGURE 104-2 Sphingolipid and ganglioside degradation defects.

type nor the location of the mutation in the gene correlates with the clinical picture. Cardiac abnormalities have been correlated with specific mutations. Patients with cardiac involvement are homozygous for certain mutations. Several mutations have been described, many in Japanese patients. A common mutation in Japan, R201C, results in a juvenile or adult variant, and the molecular defect affects interaction with the protective protein (6). Other mutations exist in Brazilian patients. An Italian mutation affects synthesis (R482H), and one in North American and Puerto Rican cases (R208C) also affects synthesis (31). The p.Arg148Cys and the p.Pro549Leu mutations are found in a homozygous state in patients with the infantile form of the disease and are correlated with a severe phenotype. The p.ArgR201His mutation is predicted to be responsible for the juvenile phenotype (32). In one case presenting as NIHF, the molecular analysis of the  $\beta$ -galactosidase gene (*GLB1*) revealed a previously unreported splicing mutation (IVS1+2 insT) in a homozygous state (33). Three novel genetic mutations in the *GLB1* coding region identified in Chinese patients with GM1 were correlated with disease severity (34). Four mutations correlated to a distinct GM1-gangliosidosis phenotype due to their occurrence in homozygous patients. The mutations directly related to infantile (c.245+1G>A, p.I181K, and p.C230R) and juvenile GM1 (p.C127Y), respectively. The patient homozygous for the mutation (p.C230R) had early and severe neurological symptoms (severe spasticity, cherry-red spots) and poor cognition, lack of cardiac dysfunction, absence of hepatosplenomegaly, and minor bony disease. Also, certain missense and nonsense mutations led to mislocalization of the mutant protein (35). The Arg482His mutation in the  $\beta$ -galactosidase gene is responsible for a high frequency of GM1-gangliosidosis carriers in a Cypriot village (36). Two novel mutations were identified in four patients of Arab descent. The splice-site mutation in the first two siblings was associated with the severe infantile type I disease, whereas the missense mutation in patient 3 was associated with the juvenile type II form of GM1-gangliosidosis. The mutation analysis of the human  $\beta$ -galactosidase gene (*GLB1*) in both the siblings revealed a homozygous mutation in intron 8; the normal nucleotide sequence of CTTgtgagt was replaced by CTTgtgggt (IVS8+4A>G). This mutation causes a splicing defect. A silent polymorphism was also found in exon 1, as well as homozygous T→C transition at nucleotide 29 (29T>C), which results in Leu→Pro substitution at amino acid 10 (L10P). A missense mutation of the human *GLB1* gene due to a homozygous G→T transversion at nucleotide 451 in exon 4 (451G>T) results in Asp→Tyr substitution at amino acid 151 (D151Y) (37). R59H is a founder *GLB1* mutation leading to infantile GM1-gangliosidosis in the Gypsy population. The R59H carrier rate is more than 2% in the general Gypsy population and greater than 10% in the Rudari subisolate. Haplotype analysis suggests that the Gypsy diaspora may

have contributed to the spread of this mutation to South America (38). Mutational analysis was performed in 19 patients from South America, mainly from Argentina. Two were of Gypsy origin. Of the 22 mutations found, 14 mutations were novel, including five deletions. Four were small, while one was a large deletion that included exon 5. All but four unrelated patients were classified as types II, III, and II/III (two cases). The two type II/III patients bore the p.R201H mutation, while the adult patient bore the new p.L155R. The juvenile patient bore two novel mutations: p.S434L and p.G554E. The two Gypsy patients were homozygous for the p.R59H mutation, previously described in other Gypsies. Analysis of another 19 unrelated South American patients uncovered 38 alleles. Fourteen mutations were novel, seven missense (p.G134V, p.L155R, p.L162S, p.S434L, p.D491Y, p.P549L, and p.G554E), one a nonsense mutation (p.W576X), one a donor splice-site mutation (c.106811G.T), and five were deletions (c.435\_440delTCT, c.845\_846delC, c.1131\_1145del15, c.1706\_1707delC, and c.458-401\_55211033del1529) (39). Mutation analysis on 30 GM1-gangliosidosis and five Morquio B patients of Spanish origin was performed and 30 different causative mutations identified, 21 of which were novel. The novel mutations p.T420K and p.L264S were associated with the adult and the juvenile forms, respectively. In addition, the novel mutation p.Y83C was associated with Morquio B disease. Of these 30 patients, six were of Gypsy origin (Roma). Moreover, those six Gypsy patients shared the same mutation (p.R59H) indicating a founder effect. Screening of the p.R59H mutation first is therefore appropriate in suspected GM1-gangliosidosis patients of Gypsy origin (40). The p.Arg595Trp mutation, frequent in the Basques population (3.2%), partially reduces  $\beta$ -galactosidase activity (41). Four other (S54N, C230Y, T329A, R442Q) and two known (R59C, R201H) mutations in the *GLB1* gene of three GM1-gangliosidosis patients represent a clinical range of the disorder that include infantile, juvenile, and adult phenotypes. In spite of mutations in *GLB1*, the infantile patients have low EBP due to defective assembly, hence considered a primary EBP defect. In the juvenile variant, EBP levels were low due to the accumulation of keratan sulfate. In summary, *GLB1* and EBP proteins, altered in function and/or distribution, contribute differently to the specific clinical manifestations of patients with mutations in the *GLB1* gene. The missense mutations detected in these patients confirm the genetic heterogeneity of GM1-gangliosidosis (30). The lack of EBP of primary and secondary origin has been linked to impaired elastogenesis in GM1-gangliosidosis patients. A reduction in EBP is linked to cardiac involvement in infantile GM1-gangliosidosis patients. *GLB1* and EBP mRNA levels were both reduced in three patients carrying splicing defects (32,36). Cardiac involvement is also reported in patients without mutations affecting the EBP protein. This may be explained by glycosphingolipid (GSL)

storage, with the inhibition of secondarily involved lysosomal enzymes and the presence of undegraded products which accumulate, such as keratin sulfate (KS). As observed in patients affected by MPS IV A (Morquio syndrome), the presence of elevated urinary glycosaminoglycan, KS in particular, could explain the patients' specific cardiac abnormalities (32). The assessment of EBP levels may prove helpful in early prognostic assessment of and decisions regarding therapy. An updated catalog of mutations of the *GLB1* gene is found in a recent review (42).

### 104.2.7 Animal Models

Naturally occurring animal models of GM1-gangliosidosis have been identified in cats, dogs (43), sheep (11), and calves. A GM1-gangliosidosis mouse model has been created through the targeted disruption of the  $\beta$ -galactosidase gene (44). Animal models show CNS manifestations. Animal models are a versatile system to test gene therapeutic approaches for GM1-gangliosidosis (45).

### 104.2.8 Therapy

Therapy is supportive. Competitive inhibitors of  $\beta$ -galactosidase in vitro can serve as stabilizers of mutant proteins in the cell serving as a chemical chaperone: *N*-octyl-4-epi-beta-valienamine and *N*-octyl beta-valienamine (NOEV) lead to a remarkable correction of enzymatic activities in cultured fibroblasts derived from some patients with GM1-gangliosidosis (46–48). NOEV, given orally to a mouse model for juvenile GM1-gangliosidosis, traversed the blood–brain barrier (BBB), increased  $\beta$ -galactosidase activity, reduced the storage of GM1 and GA1-ganglioside, and prevented neurological deterioration within a few months (49,50).

Galactose was also proposed as a potential therapeutic agent for this disease in combination with GSL synthesis inhibitors or other chemical chaperones. Galactose may be utilized to synthesize chemical derivatives with chaperone properties, as reported for the NOEV chemical chaperone (51).

Anti-inflammatory drugs may prove to be effective or helpful in the treatment of GM1 in conjunction with other treatment modalities as inflammation appears to contribute to this disease (23,52,53).

SRT is being evaluated for a number of sphingolipidoses. The goal is to decrease the rate of GSL biosynthesis to counterbalance the impaired rate of catabolism. The imino sugar *N*-butyl-deoxygalactonojirimycin (NB-DGJ), a competitive inhibitor of ceramide glucosyltransferase, reduces neonatal brain ganglioside content in a mouse model of GM1-gangliosidosis (54). This suggests that NB-DNJ may prove to be an effective early intervention in GM1-gangliosidosis. Ganglioside reductions had no adverse effects on behavior or CNS development (38). The imino sugar drugs NB-DNJ and NB-DGJ both inhibit glucosylceramide synthase (GlcCerS) (21,55) the enzyme that

catalyzes the first step in GSL biosynthesis. These drugs therefore have the potential to be used to treat all lysosomal storage diseases resulting from the storage of glucosylceramide or GluCer-based GSLs (20). These imino sugars can cross the BBB (56) and, therefore, may be used to treat GSL storage diseases with CNS manifestations. A limitation is that non-GSL substrates will continue to accumulate. NB-DGJ was better tolerated than NB-DNJ, due to the intrinsic gastrointestinal tract dysfunction that was exacerbated by NB-DNJ. Functional improvement was greatest with NB-DNJ treatment because of its additional anti-inflammatory properties (52).

Intracerebral injection of adeno-associated virus (AAV) in mice resulted in the elevation of enzyme activity throughout the CNS and normalization of GSL storage. Survival was significantly longer in AAV-treated GM1 mice than in untreated mice. The motor performance of AAV-treated GM1 mice, however, declined over time at a rate similar to that observed in untreated GM1 mice (57,58)  $\beta$ -Gal-expressing BM-derived cells selectively migrate to the CNS under a gradient of chemokines and can become a source of enzyme to neurons in patients with GM1-gangliosidosis (59). Bone marrow transplantation (BMT) was attempted unsuccessfully in juvenile GM1-gangliosidosis (60). Fetal brain cells (FBCs), BM-derived mesenchymal stem cells (MSCs), and mixed FBCs and MSCs were injected into the ventricle of newborn  $\beta$ -galactosidase knockout mouse brain with no engraftment detected at 6 months (61).

Certain cerebrospinal fluid (CSF) biomarkers could be utilized to evaluate the efficacy of novel therapies proposed for this disease (62). Periodic studies demonstrated that GM1-ganglioside concentration, activities of aspartate aminotransferase and lactate dehydrogenase, and concentrations of neuron-specific enolase (NSE) and myelin basic protein in CSF were significantly higher in dogs with GM1-gangliosidosis than those in control dogs, and correlated with age and clinical course.

## 104.3 GM2-GANGLIOSIDOSIS

### 104.3.1 Introduction

GM2-gangliosidoses are a group of lipid storage diseases caused by mutations in one of the three recessive genes, HEXA, HEXB, and the gene for GM2-activator protein (GM2A), that lead to the accumulation of GM2-ganglioside. Three different gene products are necessary for the degradation of GM2-ganglioside. These genes code for the HEXA ( $\alpha$  subunit of  $\beta$ -Hexosaminidase A on chromosome 15), HEXB ( $\beta$  subunit of  $\beta$ -Hexosaminidase A on chromosome 5), and the GM2A on chromosome 5. A defect in any one of these proteins can lead to the accumulation of GM2-ganglioside and clinical disease (63).

### 104.3.2 Clinical Presentation

**104.3.2.1 Infantile Acute GM2-Gangliosidosis.** Clinical phenotypes of the acute infantile forms of the

GM2-gangliosidosis are essentially indistinguishable. These are infantile Tay–Sachs disease (TSD) due to defects in the *HEXA* gene, Sandhoff disease due to defects in the *HEXB* gene, and the ABO variant due to defects in the *GM2A* gene. Affected infants appear normal at birth. The earliest sign of the disease is mild motor weakness, beginning at about 2 months of age. There is nonspecific slow down of growth and dullness of responses to outside stimuli. An exaggerated startle response to noise or hyperacusis is observed at an early stage. Regression and loss of already acquired psychomotor skills becomes obvious. There is progressive weakness and hypotonia with loss of gross motor skills such as sitting and crawling before 10 months of age. Seizures occur several months after the onset. Ophthalmoscopic examination often reveals macular cherry-red spots (Figure 104-3). Progression of the disease is rapid as the infant becomes less responsive to parents and surroundings. Hyperacusis, vision deterioration, and seizures are common by the end of the first year of life (64,65). The electroencephalogram shows rapidly progressive deterioration until death (66). Visually evoked potentials are abnormal, whereas the electroretinogram (ERG) is consistently normal. Macrocephaly, due to reactive cerebral gliosis, begins by 18 months of age. Further deterioration leads to decerebrate rigidity, difficulty swallowing, increasing seizure activity, and eventually a vegetative state. Death is often caused by aspiration pneumonia by the age of 4 years.

Neuroimaging studies are characterized by low density in the thalami, basal ganglia, and cerebellum on CT (67), and high signal intensity on T2-weighted images by MRI. Enlargement of the caudate nucleus is observed as the disease progresses. Brain atrophy is present in advanced disease (68). A decrease in T2 signal intensity in the thalami has also been described (16). MRI imaging modality diffusion-weighted imaging indicates that the apparent diffusion coefficient decreases in the *HEXB*–/– mouse several months before the appearance of the symptoms and could potentially be useful in assessing the severity of presymptomatic Sandhoff's disease (69). Fluorine-18 fluorodeoxyglucose-positron emission tomography (FDG-PET) scan may be a useful tool in detecting the extent of the brain lesion as it shows decreased uptake

**FIGURE 104-3** Tay–Sachs disease: fundus photograph of cherry red macula.

in affected brain regions (70). Proton MRS also is a valuable tool in monitoring disease progress and response to therapy. Results have documented a progressive and significant elevation in myo-inositol/creatine (mI/Cr) and choline/creatine ratios. A decrease in the *N*-acetyl aspartate + *N*-acetyl aspartate glutamate/creatine (NAA/Cr) ratios and decrease in the *N*-acetyl aspartate/creatine ratio have also been reported. Metabolic alterations were supportive of demyelination, inflammation, gliosis, and neuronal loss in the neuropathological process. Elevation in mI is more sensitive than other metabolite alterations (71,72). *N*-acetylhexosamine is a brain metabolite and a specific marker for Sandhoff's disease indicating accumulation of hexosamine-containing oligosaccharides (73). This interpretation is supported by a recent in vitro MRS study of a Sandhoff mouse model (74).

**104.3.2.2 Late-Onset Forms.** Disease onset can be at any time from the late infantile period to adult age. There is involvement of the deeper brain structures and less of cortex in comparison to the overwhelming gray matter involvement in the infantile form. Manifestations include dystonia, ataxia, spinocerebellar degeneration, and lower motor neuron disease. In the adult-onset form of TSD, an amyotrophic lateral sclerosis-like or ALS-like motor neuron involvement and psychosis develop (75–78). Rarely, it may mimic primary lateral sclerosis (79). Late-onset forms of GM2-gangliosidosis can occur as variant forms of TSD or Sandhoff disease. GM2-activator deficiency only results in infantile GM2-gangliosidosis, indistinguishable from infantile TSD or Sandhoff disease (80). Some medications, particularly haloperidol, risperidone, and chlorpromazine, have been reported to result in neurologic worsening in late-onset forms of the disease (81). In most cases, the later onset forms of expression result from the presence of at least one allele (usually the G269S mutation) associated with residual enzyme ( $\beta$ -hexosaminidase A) activity. A positive family history is a valuable clue, enabling early diagnosis. Nonspecific cerebellar atrophy on brain imaging is another important finding. This entity should be considered in patients with speech, gait, and balance problems, and with psychiatric disorders even when focal neurologic deficiencies are absent (82). Isolated stutter is sometimes the sole initial manifestation of late-onset TSD years before developing other manifestations (83). Changes in metabolites on MRS closely reflect clinical features. Follow-up examination by MRS is useful for evaluation of neuronal changes, even prior to major anatomical changes associated with late-stage clinical disease (74). MRS might be a sensitive method for detecting and quantifying neuroaxonal injury and monitoring response to emerging treatments even in the absence of radiologic abnormalities on conventional MR imaging (84).

**104.3.2.3 Subacute GM2-Gangliosidosis.** Generally, ataxia develops between 2 and 10 years of age. Developmental regression and dementia are leading features of this variant. Progressive psychomotor deterioration, increasing spasticity, and seizures develop by the end of the first decade of life (80). Optic atrophy and retinitis

pigmentosa may be seen late in the course of this condition, and are the main reasons for visual loss. A vegetative state with decerebrate rigidity develops by 10–15 years of age, followed by death, usually precipitated by aspiration pneumonia. In some cases, the disease takes on a particularly aggressive course, with death occurring between 2 and 4 years of age (85). This subacute phenotype has been described in patients with HEXA or HEXB mutations.

**104.3.2.4 Chronic GM2-Gangliosidosis.** Clinical onset is anywhere from childhood to adulthood (75). Variations in clinical manifestations and clinical course are extreme. TSD variants are more common than Sandhoff disease variants. Dystonia and extrapyramidal signs are common. The clinical phenotype is similar in some cases to that seen in Friedreich's ataxia. Cerebellar signs can be the major symptoms (78,86). In some cases, prominence of cerebellar symptoms, along with spasticity and muscle wasting, suggest an atypical form of Friedreich's ataxia with normal or increased deep tendon reflexes (87). A number of older patients have a pattern of muscle wasting and weakness with fasciculation and secondary skeletal abnormalities indistinguishable from late-onset spinal muscular atrophy or Kugelberg–Wielander disease (88). In others, the condition resembles ALS. In some cases of chronic Sandhoff disease, autonomic nervous system involvement is pronounced and may include achalasia (89). Most patients with late-onset GM2-gangliosidosis have upper rather than lower motor neuron abnormalities. Electromyography (EMG) findings are consistent with chronic active denervation with re-nerivation. Nerve conduction velocities are usually normal, and muscle biopsy shows denervation atrophy. EEG is generally unremarkable, and rectal biopsy shows the membranous cytoplasmic bodies (MCBs) seen in the severe clinical variants of GM2-gangliosidosis. Neuroimaging studies demonstrate severe cerebellar atrophy with some cerebral atrophy (88). Psychiatric abnormalities are relatively common, affecting as much as 40% of patients with the disease. This may be the most notable feature of the condition, and can range anywhere from depression to schizophrenia.

**104.3.2.5 Pathology.** Due to gliosis, brain weight and volume increase during the second year of life. Cystic degeneration of the cerebral white matter, along with atrophy of the cerebellar hemispheres, is frequently present. In the brain, neuronal number is diminished, and remaining neurons appear ballooned due to the stored material (Figure 104-4). Glial cells are also engorged. Spinal anterior horn cells are affected. This explains the hypotonicity, hyporeflexia, and weakness. Lipid-laden macrophages are present in liver, spleen and lung. Electron microscopy reveals lipid-laden lysosomes located throughout the cytoplasm of neurons. In late-onset GM2-gangliosidosis, storage is preferentially localized to the thalamus, substantia nigra, cerebellum and brainstem nuclei. This is a progressive neurodegenerative disease caused by GM2-ganglioside accumulation in lysosomes giving rise to membranous cytoplasmic bodies or MCBs,

**FIGURE 104-4** GM2 gangliosidosis brain with ballooned neuron.

which also contain cholesterol and sphingolipid. There is apoptosis of vulnerable neurons. Phagocytic clearance leads to chronic inflammation involving elevated cytokine production and reactive oxygen/nitrogen species. A compromised BBB amplifies inflammation even further and promotes secondary oxidative stress, leading to apoptosis and neurodegeneration. Jeyakumar et al. demonstrated that microglial/macrophage activation plays a key role in the pathological process in mouse models for GM1-/GM2-gangliosidoses (23).

Both late endosomes and lysosomes, not early endosomes, have a higher density in Sandhoff fibroblasts. These have an intracellular distribution of terminal endocytic organelles different from the perinuclear punctate pattern observed in normal fibroblasts and endocytic vesicles are larger. This alteration in the terminal endocytic organelles of Sandhoff fibroblasts suggests the involvement of this compartment in the disruption of cell metabolic and signaling pathways leading to the pathological state (90). Autopsy studies of late-onset GM2-gangliosidosis are sparse with one adult case on record. The autopsy findings show severe accumulation of lipid and regressive changes in the anterior horns of the spinal cord. Less-severe storage was found in other spinal cord neurons, brainstem and selected basal ganglia. Cerebral cortex was virtually spared from storage but was the site of excessive lipofuscin, also present in many other neurons in the CNS. The involvement of sensory neurons was prominent and potentially related to allodynia. Marked storage and ganglionic loss were also found in the dorsal root ganglia, and the fasciculus gracilis was severely depleted of myelinated fibers. Electron microscopy showed homogeneously accumulated gangliosides in the form of single and coalescing zebra bodies, contrasting with heterogeneity of neuronal inclusions found

in other chronic cases. In Sandhoff mice, neuronal cells and pigment epithelial cells are vulnerable to excess ganglioside more than other retinal cells, as demonstrated by cytoplasmic inclusions and vacuolations (91).

**104.3.2.6 Biochemistry.** The defect in GM2-gangliosidosis is caused by the failure of  $\alpha$ -hexosaminidase to hydrolyze the terminal amino sugar from GM2-ganglioside. Disease severity correlates inversely with the amount of residual enzyme activity. The enzyme exists as two isoenzymes,  $\beta$ -hexosaminidase A (HEXA) and  $\beta$ -hexosaminidase B (HEXB). HEXA ( $\alpha\beta$ ) is a thermolabile protein composed of a dimeric structure of  $\alpha$  and  $\beta$  subunits, whereas HEXB ( $\beta\beta$ ) is a heat-stable dimeric structure composed of two  $\beta$  chains. A GM2A is essential for the hydrolysis of GM2-ganglioside. HEXA and HEXB hydrolyze *N*-acetylhexosamine from glycoproteins, glycolipids, glycosaminoglycans and oligosaccharides. HEXA metabolizes GM2-ganglioside. HEXB metabolizes globoside as well as the compounds listed previously. In humans, GM2 is degraded in the lysosome by  $\beta$ -hexosaminidase A, which removes the *N*-acetyl-galactosaminyl group. Yet, the water-soluble enzyme cannot hydrolyze the membrane-bound GM2 due to steric hindrance by the membrane surface. GM2-A is necessary to present the GM2-ganglioside lipid to the water soluble enzyme for terminal sugar hydrolysis. The hexosaminidases and GM2-A are glycoproteins that are synthesized in the endoplasmic reticulum (ER) lumen and processed in the Golgi. They are transported via the mannose-6-phosphate receptor to the lysosome. Both  $\alpha$  and  $\beta$  subunits possess an active site, yet dimer formation, as HEXA ( $\alpha\beta$ ), HEXB ( $\beta\beta$ ), and HEX S ( $\alpha\alpha$ ) are required for catalytic activity. The  $\alpha$  and  $\beta$  subunits exhibit different substrate specificities. The  $\beta$  subunit preferentially hydrolyzes neutral water-soluble substrates. The  $\alpha$  subunit also hydrolyzes negatively charged substrates such as GM2-ganglioside, dermatan sulfate, and chondroitin sulfate. The primary amino acid sequences of  $\alpha$  and  $\beta$  chains share a great degree of primary structure homology. Also, the gene structures of HEXA and HEXB are similar with respect to the number and placement of intron/exon junctions (64,92). Twelve of the 13 introns interrupt the genes at corresponding positions. The GM2 activator gene is 16 kb long and contains four exons.  $\alpha$ -Subunit defects result in HEXA deficiency (TSD and juvenile and adult-onset GM2-gangliosidosis);  $\beta$  subunit defects affect HEXA and HEXB (Sandhoff's disease), and defects in the GM2-A results in normal HEXA and HEXB activities with accumulation of GM2-ganglioside (the ABO variant). In the B1 variant, described mainly in Portuguese patients, there is a defect in the  $\beta$  catalytic site. Enzyme activity loss in the latter variant can only be demonstrated when a sulfated artificial substrate is used to assay enzyme activity. Loading studies of fibroblasts with radiolabeled gangliosides can help identify all these variants, but is particularly useful for identifying the B1

and ABO variants (93). In GM2-gangliosidosis, GM2 is markedly increased in the nervous system, representing ~90% of neutral tissue gangliosides. GM2 is also stored in the liver and spleen. Asialo and Lyso forms of GM2 are also increased in brain tissue of GM2-gangliosidosis patients. Lyso compounds are cytotoxic and are also present in the brains of patients affected by MLD, Krabbe disease and Gaucher disease. The acute forms of GM2-gangliosidosis are associated with complete HEXA deficiency and early death. Enzyme activity levels of ~5% are present in the juvenile and adult forms. Some unaffected individuals have only 10% enzyme activity compared with normal controls. Sandhoff and Conzelmann have estimated that 5–10% of normal HEXA activity levels represent a “critical threshold” below which disease exists (94).

Astrocytes were isolated from the neonatal brain of Sandhoff disease model mice in which the *N*-acetyl- $\beta$ -hexosaminidase  $\beta$  subunit gene is genetically disrupted (ASD). Results indicated that the upregulation of extracellular signal-regulated kinase (ERK) phosphorylation and the increase in proliferation of ASD astrocytes were dependent on GM2/GA2 accumulation. The phosphorylation of ERK in ASD cells was not dependent on extracellular growth factors. Treatment of ASD astrocytes with recombinant *N*-acetyl- $\beta$ -hexosaminidase A resulted in a decrease of their growth rate and ERK phosphorylation. These findings may represent a mechanism linking nerve cell death and reactive gliosis in Sandhoff disease (95).

Another theory about neurodegeneration in GM2-gangliosidosis implicates altered iron homeostasis. Progressive depletion of iron in brain demonstrated in mice seems to correlate with neurodegeneration. Key regulators of iron homeostasis, hepcidin and IL-6, are increased in gangliosidoses mice. In the brain, the principal iron transport and delivery protein transferrin is reduced, as is the ability of the brain to acquire iron from the circulation. Expression of the transferrin receptor was upregulated reciprocally. Administration of iron prolonged survival in the diseased mice by up to 38%, with onset of disease delayed and motor function was preserved (28).

There is a functional role for Sphingosine-1-phosphate (S1P) synthesis and receptor expression in astrocyte proliferation leading to astrogliosis during the terminal stages of neurodegeneration in Sandhoff disease mice. When sphingosine kinase 1 (Sphk1) is deleted in Sandhoff disease mice, a milder disease course occurred, with decreased proliferation of glial cells and less-pronounced astrogliosis. Astrocyte responses are involved in many types of neurodegeneration, and the sphingosine kinase 1/sphingosine-1-phosphate (Sphk1/S1P) receptor signaling axis may be important during the pathogenesis of neurodegenerative diseases (96).

There is accumulation of  $\alpha$ -synuclein in brain tissue of some lysosomal storage diseases, in both neurons and glial cells.  $\beta$ -Synuclein was detectable only in the pons of Sandhoff disease cases. This differential accumulation of

$\alpha$ - and  $\beta$ -synucleins in human lipidoses may be related to functional differences between these two proteins (97).

**104.3.2.7 Genetics.** The majority of mutations cause the severe infantile onset disease. Several mutations are responsible for certain subtypes of HEXA deficiency. The B1 subtype includes HEXA mutations in the catalytic  $\beta$ -subunit domain. They do not interfere with the synthesis and the activity of the HEXA heterodimer, but the enzyme is inactive toward the sulfated artificial fluorescent substrate used to determine enzyme activity, 4MUGS, as well as the natural substrate, GM2-ganglioside. Mutations causing the chronic disease phenotypes result in an unstable protein that fails to associate with the  $\alpha$  subunit or is otherwise incompletely processed. HEXA pseudodeficiency is due to a point mutation that leaves HEXA with lower activity toward the artificial substrate, but with sufficient GM2-ganglioside hydrolyzing activity to escape disease.

TSD occurs more commonly in Ashkenazi Jews, French Canadians from eastern Quebec, Cajuns from Louisiana, and Pennsylvania Dutch. About 1 in 3600 Ashkenazi Jews are at risk for TSD. However, TSD is not only restricted to these groups, but occurs in all ethnic groups. Juvenile TSD has no ethnic predominance. Inheritance is autosomal recessive. TSD is genetically heterogeneous, and multiple allelic mutations have been described. Even in single ethnic groups, multiple mutations exist. More than 75 mutations of the gene for the  $\alpha$  subunit are known. These mutations can result in wide variations in residual enzyme activity, extent and distribution of GM2-ganglioside accumulation in the brain and spinal cord, and great diversity of clinical phenotypes. An online database enumerating alleles, mutations, phenotypes, and authors is available. Only four mutations have been documented in the gene for the GM2A.

Gene sequencing detected four novel mutations, three of which are predicted to be disease causing [118.delT, 965A3T (D322V) and 775A3G (T259A)]. Six novel mutations are also described: one large deletion of 2406 nt (c.299+1471\_408del2406), one frameshift mutation c.965delT (p.I322fsX32), one nonsense c.1372C>T (p.Q458X), and three splicing mutations (c.299G>T, c.300-2A>G and c.512-1G>T) (98). A homozygous missense HEXB mutation (p. D459A) was discovered in six patients with a rare juvenile variant disrupting a salt bridge between aspartate D459 and arginine 505 at the subunit interface. R505 mutations are reported in late-onset Sandhoff disease (99).

A novel c.1556A>G transition in exon 12 of the *HEXB* gene associated with chronic Sandhoff's disease changes a conserved aspartic acid to glycine at position 494 of the Hex  $\beta$ -subunit. This A>G transition affects both *HEXB* mRNA processing and biochemical properties of the  $\beta$  subunit (100).

Of 31 Italian patients, 22 with the infantile, acute form of TSD and 9 with the subacute juvenile form, biochemically classified as B1 variant, are reported: Of the 29 different alleles identified, 14 are due to 15 novel mutations, two being *in-cis* on a new complex allele (101).

In patients with the Tay-Sachs variant, the presence of R178H and R499H mutations was predictive of an early onset and rapidly progressive course. The presence of either G269S or W474C mutations was associated with a later onset of symptoms along with a more slowly progressive disease course (102).

A 2-year-old black child with juvenile-onset disease, who presented with abnormal eye movements and cherry-red spots of the maculae, was a compound heterozygote (M1V/Y37N) of the *HEXA* gene. The M1V mutation was previously described in an African-American child with acute infantile GM2-gangliosidosis. The Y37N mutation is novel. This combination of mutations is consistent with the juvenile-onset disease, and provides further evidence for the association of the M1V mutation with individuals of black ancestry. The presence of oculomotor abnormalities is an unusual finding in this form of GM2-gangliosidosis, and adds to the phenotypic spectrum (103).

Gene sequencing is useful in identifying rare mutations in patients with TSD and their families, in evaluating spouses of known carriers for TSD who have indeterminate enzyme analysis and are negative for common mutation analysis, and in resolving ambiguous enzyme testing results (104).

### 104.3.3 Diagnosis and Carrier Detection

With the development of specific enzymatic and molecular diagnostic methods, ascertainment of carriers and affected patients can be achieved with readily available tissues or body fluids, such as serum, tears, chorionic villi, skin fibroblasts, leukocytes and buccal mucosa cells. In a given family, with a known mutation, specific prenatal and postnatal diagnosis of the heterozygous, homozygous, or compound heterozygous state, can be made by direct DNA analysis. The availability of rapid and inexpensive methods for identification of carriers has made it possible to develop programs for screening of populations at risk. Furthermore, coupling this with DNA-based diagnostics allows distinction between infantile, subacute, and chronic disease mutations, as well as pseudodeficiency alleles that do not result in disease. Carrier frequencies are 0.006 for *HEXA* mutations and 0.0036 for *HEXB* mutations. Among Ashkenazi Jews, the carrier frequency for *HEXA* mutations is as high as 0.033. Successful screening programs targeting Ashkenazi Jewish groups have resulted in a drastic reduction in the incidence of this fatal disease in this population by almost 90%. The adult-onset form, which presents with lower motor neuron symptoms and signs of psychosis, has primarily been described in those of Ashkenazi Jewish descent. They carry the common Ashkenazi mutation on one allele, and a milder mutation on the other allele. It is this second allele that defines the less severe phenotype. Other groups at high risk for TSD include Pennsylvania Dutch, Louisiana Cajun, and French Canadian populations. Epidemiologic studies have found a high carrier rate up to 1/52 in Irish Americans (105). Current

guidelines limit testing to selected high-risk groups and may miss potential carriers, despite the availability of an inexpensive enzyme screen. More than 100 mutations in the hexosaminidase A gene have been identified, some associated with later onset or chronic forms. HEXA enzyme analysis, HEXA DNA common mutation assay, and *HEXA* gene sequencing improve the sensitivity for carrier detection in non-Ashkenazi individuals. Sensitivity of TSD carrier detection is 91% for gene sequencing compared with 91% for the enzyme assay and 52% for the common DNA assay. Gene sequencing combined with enzyme testing had the highest sensitivity (100%) for carrier detection. This has important implications if TSD population screening is expanded to non-Ashkenazi Jewish populations (104).

Molecular analysis yields a false negative rate of 11.4% with a sensitivity of 88.6%. Due to changing demographics of the Ashkenazi Jewish population, molecular testing alone is not sufficient and biochemical analysis should be the assay of choice. Platelet *HEXA* enzyme assay is associated with a very high detection rate (1 in 29; 3.4%) and a very low inconclusive rate (0.4%). Platelet assay is superior to serum with an inconclusive rate that is 40-fold lower (106).

An accurate and fast isotope dilution tandem mass spectrometry method for the simultaneous measurements of GM1 and GM2 in human CSF samples measures ganglioside content in the CSF of patients with TSD, including presymptomatic cases. This assay is important for evaluating therapeutic effects of ganglioside elimination (107).

Prenatal diagnosis of TSD disease is accomplished within 24–48 h from sampling. The preferred strategy is to simultaneously carry out enzymatic analysis in the amniotic fluid (AF) supernatant or chorionic villi and molecular DNA-based testing of an AF cell-pellet or chorionic villus sample (CVS) (108). If the affected alleles are known from previous affected siblings or pregnancies, qPCR assays offer a sensitive and rapid technique for allelic discrimination (13).

Based on the preceding information, the Committee on Genetics makes the following recommendations:

- (1) Screening for TSD should be offered before pregnancy if both members of a couple are of Ashkenazi Jewish, French-Canadian, or Cajun descent. Those with a family history consistent with TSD also should be offered screening.
- (2) When one member of a couple is at high risk (of Ashkenazi Jewish, French-Canadian, or Cajun descent or has a family history consistent with TSD) but the other partner is not, the high-risk partner should be offered screening. This is particularly important if there is uncertainty. If the woman is already pregnant, it may be necessary to offer screening to both partners simultaneously to ensure that results are obtained promptly and that all options are available to the couple.

- (3) Biochemical analysis should be used for individuals in low-risk populations.
- (4) If TSD biochemical screening is performed in women who are pregnant or taking oral contraceptives, leukocyte testing must be used.
- (5) Ambiguous screening test results or positive screening test results in individuals should be confirmed by biochemical and DNA analysis for the most common mutations. This will detect patients who carry genes associated with mild disease or pseudodeficiency states. Referral to a geneticist may be helpful in these cases.
- (6) If both partners are determined to be carriers of TSD, genetic counseling and prenatal diagnosis should be offered (109).

Education and counseling are clearly important components of screening, and issues of privacy and confidentiality must be addressed, as well as insurability and employment. Conflict of interest by entrepreneurial scientists, clinicians, institutions and other advocates of widespread screening are also potential concerns (110).

### 104.3.4 Animal Models

GM2-gangliosidosis has been reported in dogs (111), cats, mice (112), and pigs. They all exhibited neuronal storage, but visceral storage was only found in the feline model.

Feline GM2-gangliosidosis is unique among large animal models of disease in the number and variety of mutations that have been reported (113). GM2-activator deficiency has been described in humans, dogs, and mice (114).

An animal model (American Flamingo, *Phoenicopterus ruber*) of TSD with HexA deficiency occurs spontaneously in nature. The spontaneous appearance of this animal model of TSD with features similar to those of the human form of this disorder could be a possible research tool for further studies of pathogenesis and the treatment of TSD (70).

### 104.3.5 Therapy

Therapy is primarily supportive. Several approaches to therapy are being investigated in animal and cell culture models. Most gene therapy experiments have involved the production of a recombinant virus, either retrovirus or adenovirus containing the *HEXA* cDNA. Substrate deprivation therapy has been tested by oral administration of NB-DNJ in Tay–Sachs mice, resulting in a 50% reduction in GM2-ganglioside accumulation (21,54,115). Other approaches still under investigation and research are bone marrow (BM) and neural progenitor cell transplantation. The attractiveness of SRT is that it is oral therapy and that the drug crosses the BBB and can act centrally. Also, risks and complications are relatively minor. Enzyme replacement is much less effective in diseases that primarily affect the CNS because of the difficulty of large molecules to cross the BBB. Theoretically, BM or cord blood transplantation should provide some enzyme-producing glial cells to the

CNS, but the high morbidity and mortality and the doubtful effectiveness of this approach make it undesirable, particularly in light of the low chance of efficacy. Unfortunately, these therapies have less than optimal chances at making a difference, as in most cases, once the diagnosis is made, considerable CNS damage has already occurred.

Recombinant human  $\beta$ -hexosaminidase A is a potentially therapeutic enzyme for GM2-gangliosidosis. Recombinant HEXA produced from certain yeasts and lentiviral (LV) vectors is effectively incorporated into cultured fibroblasts and neural cells, and rapidly degrades GM2-ganglioside in vitro (116–118). Gene transfer strategies using nonreplicating Herpes simplex vector encoding for the HexA  $\alpha$  subunit succeeded in replacing the missing enzyme in Tay–Sachs animal models when injected in the internal capsule of the affected mice without adverse effects (119). Similarly, hippocampal neurons and microglia of Sandhoff disease animal models were transduced with lentiviral and adeno-associated viral vectors encoding the Hex  $\beta$  subunit. This resulted in the elimination of the intracellularly accumulated GM2 in the brain and spinal cord, reduction of inflammation, preservation of motor power, and increased survival (120–122). Neonatal intraperitoneal administration led to reduction in neuroinflammation, attenuation of GM2 storage and amelioration of neurodegeneration and motor behavioral deterioration (118). SRT aims to decrease the rate of GSL biosynthesis to compensate for slowed catabolism. The imino sugar, NB-DGJ inhibits the first step in GSL biosynthesis. NB-DGJ treatment, administered from postnatal day 2–5 (600 mg/kg/day), significantly reduced total brain ganglioside and GM2 content in Sandhoff disease (Hexb $^{-/-}$ ) mice. NB-DGJ is effective in reducing total brain ganglioside and GM2 content at early neonatal ages (123).

In a multicenter, open-label, 12-month study involving patients aged 18 years or older randomized to miglustat (Zavesca) (200 mg TID) or “no miglustat treatment,” miglustat treatment did not lead to measurable benefits in late-onset TSD (124). In another open-label study over a 24-month period, five juvenile GM2 patients on oral miglustat at doses of 100–200 mg t.i.d. did not improve from a motor standpoint, but had stabilization of brain MRI lesions and some aspects of cognitive function over 24 months (125–127). Miglustat is a safe drug. Major adverse events in infantile patients include abdominal discomfort and flatulence, and in the juvenile group, diarrhea and weight loss (128).

One promising therapy for GM2-gangliosidosis involves the use of beta-*N*-acetylhexosaminidase inhibitors as chemical chaperones to enhance the enzyme activity above subcritical levels. Pharmacological chaperones (PC) are small molecules that can stabilize the conformation of a mutant protein, allowing it to pass the quality control system of the ER. They are used as enzyme enhancement therapy agents that are competitive inhibitors of the target enzyme beta-*N*-acetylhexosaminidase and may be useful as therapeutic agents for treating adult TSD and Sandhoff disease. The L-iminosugar LABNAc

and its derivatives are potent noncompetitive inhibitors of some beta-*N*-acetylhexosaminidases, while the D-iminosugar DABNAc and its derivatives were found to be weaker competitive inhibitors (129).

Pyrimethamine, a potent inhibitor, functions as a mutation-specific PC, enhancing residual lysosomal HEXA levels in late-onset GM2 patient cells (130).

Intracranial injection of neural stem cells (NSCs) into the brain of adult symptomatic Sandhoff (Hexb2/2) mice, results in cell migration far from the injection site and integration into the host cytoarchitecture, restoring  $\beta$ -hexosaminidase enzyme activity and promoting neuropathologic and behavioral improvement. Mouse life span increased, neurological function improved, and disease progression slowed. Clinical benefits correlated with neuropathological correction at the cellular and molecular levels, reflecting enzyme cross-correction, cell replacement, tropic support, and direct anti-inflammatory action. Pathotropism (i.e. migration and homing of NSCs to pathological sites) could be imaged in real time by MRI. Differentially expressed chemokines might play a role in directing the migration of transplanted stem cells to sites of pathology. Significantly, the therapeutic impact of NSCs implanted in even a single location was surprisingly widespread due to both cell migration and enzyme diffusion. Because many of the beneficial actions of NSCs observed in newborn brains were recapitulated in adult brains to the benefit of Sandhoff recipients, NSC-based interventions may also be useful in symptomatic subjects with established disease (125). In addition to neuronal replacement, NSCs also increased brain  $\beta$ -hexosaminidase levels, reduced ganglioside storage, and diminished activated microgliosis. When oral GSL biosynthesis inhibitors ( $\beta$ -hexosaminidase substrate inhibitors) were combined with NSC transplantation, substantial synergy resulted. Efficacy extended to human NSCs, both to those isolated directly from the CNS and to those derived secondarily from embryonic stem (ES) cells (131).

Trials of bone marrow transplantation (BMT) failed to ameliorate the natural course of the disease (132). Immunomodulation by inhibition of infiltrating peripheral blood mononuclear cells (PBMC) infiltration in the HexB $^{-/-}$  mouse model of Sandhoff disease brain retards disease progression and neurodegeneration in a mouse model of GM2-gangliosidosis. Ablation of the chemokine receptor CCR2 in the Hexb $^{-/-}$  mouse resulted in significant inhibition of PBMC infiltration into the brain, decrease in TNF- $\alpha$  and MHC-II mRNA abundance, and retardation in clinical disease development (133).

Caloric restriction may be effective in improving motor coordination and extending longevity in Hexb $^{-/-}$  mice during the symptomatic phase of SD, when extensive inflammatory processes are active. Furthermore, this improvement was observed without changes in brain GSL composition or cytoplasmic neuronal vacuoles and was not associated with observable adverse effects (134).

## 104.4 LOSS-OF-FUNCTION MUTATION OF GM3-SYNTASE

### 104.4.1 Introduction

Most disorders discussed under sphingolipidoses have involved hydrolysis enzyme defects. Although the existence of a sphingolipid class synthesis disorder has been postulated for a long time, this is the first report in humans of a documented molecular defect. The importance of this first description of a GM3-synthase disorder in humans suggests that other enzymes involved in the synthesis of gangliosides or other sphingolipids or glycolipids might be products of candidate genes at the root of other epilepsy syndromes (1,135).

### 104.4.2 Clinical Description

The first symptoms appear between 2 weeks of age and 3 months and consist of irritability, poor feeding, and failure to thrive. Generalized tonic-clonic seizure activity begins before 1 year of age. Other seizure types, resistant to therapy, including startle myoclonus, set in. Once seizures begin, complete developmental stagnation and regression are the norm. Affected children are mute, nonambulatory, and do not reach for objects, but have nonpurposeful choreoathetoid movements. They are cortically blind and some develop optic atrophy. EEG is slow with superimposed epileptiform discharges. MRI demonstrates progressive cortical atrophy.

### 104.4.3 Biochemistry

The protein catalyzes the formation of GM3-synthase from lactosylceramide, and is the initial and most crucial step in the formation of complex a- and b-series gangliosides. Affected children completely lack GM3 and its downstream derivatives in their serum, but accumulate the precursor, lactosylceramide, and show evidence of increased flux through the globoside and paragloboside alternate pathways. It is not known whether this severe neurological impairment is due to the lack of GM3 and its derivatives, or results from accumulation of precursors. In some studies, pharmacological depletion of cellular gangliosides did not impede stimulated neurite outgrowth (136) or neuronal differentiation of cultured cells suggesting yet other explanations for the neurological deficits (137).

### 104.4.4 Genetics

Simpson and associates (1) reported GM3 synthase deficiency in a large, older Amish pedigree. The defect is inherited in an autosomal recessive manner. All cases have a nonsense mutation in the *SIAT9* gene (R232X), which codes for the GM3 synthase enzyme.

### 104.4.5 Animal Models

A line of mutant mice with the same defect have a mild phenotype with increased insulin but no seizures, in contrast to the severe phenotype in humans. Mice lacking ganglioside GM3 synthase exhibit complete hearing loss due to selective degeneration of the organ of Corti (138). Mice unable to synthesize ganglioside GM3 are viable and do not have major abnormalities (139), but mice carrying double null mutations in both GM2 and GM3 synthases develop severe neurodegenerative diseases that result in death (140). Histopathological examination revealed striking vacuolar pathology in the white matter regions of the CNS with axonal degeneration and perturbed axon–glia interactions.

### 104.4.6 Treatment

Treatment is largely supportive at this point and encompasses nutritional management and seizure control. Seizures are notoriously difficult to control necessitating polypharmacy and vagal nerve stimulators. Most children have required feeding tubes.

## 104.5 NIEMANN–PICK DISEASE

### 104.5.1 Introduction

Niemann–Pick disease (NPD) constitutes a heterogeneous group of lysosomal storage diseases with an autosomal recessive mode of inheritance. Four clinical forms are described, which were initially grouped together because of pathologic similarities of the cases and the appearance of sea-blue histiocytes in the reticuloendothelial system. Types A and B caused by low acid sphingomyelinase (ASM) activity are characterized by the accumulation of sphingomyelin and arise because of defects in the same gene (141). Type C1, which includes an allelic variant from a genetic isolate from Nova Scotia, formerly delineated as Niemann–Pick, type D, accounts for 95% of Niemann–Pick, type C, cases. More recently, a second gene, NP-C2, has been identified. Niemann–Pick, types C1 and C2 defects, result in a distinctive lipid trafficking perturbation of low density lipoprotein (LDL)-derived cholesterol that remains trapped in the lysosomal compartment. Sphingomyelin, as well as other lipids, are increased secondary to abnormal cholesterol sequestration in lysosomes (142).

## 104.6 NIEMANN–PICK DISEASE, TYPES A AND B

### 104.6.1 Clinical Presentation

**104.6.1.1 Niemann–Pick Disease, Type A (Infantile or Acute Form).** Typically, hepatosplenomegaly develops in the first few months of life along with

moderate lymphadenopathy. There is a preponderance of NP-A Ashkenazi Jewish cases. The abdomen becomes protuberant. A moderate microcytic anemia, which may be responsive to iron, and a decrease in platelet counts occur later. Neurologic findings include hypotonia and muscular weakness (feeding difficulties). Recurrent vomiting and constipation are main complaints. About 50% of patients have macular cherry-red spots. ERG responses are diminished and EEG shows nonspecific slowing and voltage attenuation. Auditory-evoked brainstem responses may be abnormal, and nerve conduction velocities may be reduced. Death ensues at 4 years after a relentless neurodegenerative course. Early laboratory markers of disease include elevated levels of serum glutamic oxaloacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), total cholesterol, and triglycerides (TGs) and low HDL-C (143).

**104.6.1.2 Niemann–Pick Disease, Type B (Chronic, Non-Neuronopathic Forms).** Type B is known as the chronic, non-neuronopathic form because of prolonged survival and the absence of neurologic involvement. Hepatosplenomegaly is particularly prominent in childhood. In most type B patients, decreased pulmonary diffusion due to alveolar infiltration becomes evident in childhood and progresses with age. Patients may experience significant pulmonary compromise by 15 years of age. This is usually manifested with low oxygen tensions in the blood, dyspnea on exertion, bronchopneumonias that may be life threatening, and cor pulmonale. Severely affected patients may have liver involvement and eventually develop cirrhosis. Rarely, joint and bone pain may be the presenting symptoms (144). In general, type B patients do not have neurologic involvement and are intellectually intact. Some NP-B patients have cherry-red maculae or a gray granular pigmentation around the fovea that appears like a halo (145). Two adults with psychiatric and pulmonary disease and low ASM activity have been described (146). The oldest patient at the time of diagnosis was a 68-year old woman (147). Fifty-nine demographically diverse patients demonstrate multisystem involvement and clinical variability of Niemann–Pick B disease. Most of them initially present with splenomegaly (78%) or hepatomegaly (73%). Frequent symptoms include bleeding (49%), pulmonary infections and shortness of breath (42% each), and joint/limb pain (39%). Growth is markedly delayed during adolescence. Patients commonly have low levels of platelets and HDL, elevated levels of LDL, Very low density lipoprotein (VLDL), TG, leukocyte sphingomyelin, and serum chitotriosidase, and abnormal liver function test results (148). NPD type B also can affect the cardiovascular system due to the abnormal lipid profiles. In addition to abnormalities in LDL and TG, patients have elevated cholesterol and low HDL, which lead to accelerated atherosclerotic heart disease, with coronary artery calcification in both children and adults (149). Massive

pulmonary involvement in early life is extremely rare. An infant presenting with recurrent respiratory tract infections has been reported (150). Patients commonly show restrictive lung disease physiology with impaired pulmonary gas exchange and decreased maximal exercise tolerance (148). Radiographically, pulmonary involvement manifests as a reticulonodular pattern, interlobular septal thickening, ground-glass density, and subcentimeter, sometimes calcified nodules. On occasion, the combination of these findings will result in the “crazy-paving” sign seen on CT in a variety of diseases. The imaging findings generally begin in the bases and progress cranially. Rarely, pulmonary nodules and cysts are described (151). The aurora sign, a sonographic sign found on the sagittal and transverse view, referring to multiple bands of ring-down artifacts posterior to the right hemidiaphragm has been reported in a patient with NPD type B (152). Imaging features do not necessarily correlate with the degree of pulmonary function impairment (153).

Cardiac dysfunction is not a usual complication in this disease, and is usually secondary to cor pulmonale. Recently, myocardial dysfunction without pulmonary disease was reported in two sisters in their third decade (genotype: S436R/S436R). The cardiac involvement was refractory to treatment in one, resulting in death (154).

Abdominal manifestations include hepatosplenomegaly, but adrenals, kidneys, and retroperitoneal lymph nodes can be involved (149). Splenomegaly is a prominent clinical manifestation of NPD type B, which occurs because of the accumulation of lipid-laden macrophages in the reticuloendothelial system (RES). Splenic masses are typically echogenic on ultrasound and low density on CT, and can have variable signal characteristics on MRI, with the most common being isointensity on T1-weighted images and high signal on T2-weighted images (149). The degree of splenomegaly correlates with most aspects of disease, including hepatomegaly, growth, lipid profile, hematologic parameters, and pulmonary function. Spleen volume correlates with disease severity, and may be a useful surrogate end point in treatment trials (148).

Hepatomegaly is also a prominent clinical finding in patients with NPD type B. The liver enlarges because of the accumulation of lipid-laden macrophages in the RES of the liver. Abnormal liver function tests and in rare cases, cirrhosis and hepatic failure can occur. The liver can be imaged with ultrasound, CT, or MRI. Repeated imaging studies are necessary to monitor disease and MRI is the modality of choice. CT, however, is better for detection of small foci of calcium in the liver and other organs (149). Niemann–Pick cells infiltrate the bone marrow (BM), leading to leukopenia and thrombocytopenia with normal hemoglobin levels. Adolescent patients with NPD type B have delayed skeletal maturation and growth restriction. Patients may have osteopenia or osteoporosis, detectable radiographically. MRI shows low T1 signal in the BM. Adrenal glands, kidneys, and lymph nodes can be involved in NPD type B and

have intermediate signal on T1- and T2-weighted imaging by MRI (149,155).

### 104.6.2 Pathology

The hallmark of this disease is the histochemically characteristic lipid-laden cells known as foam cells. These appear as sea-blue histiocytes in the BM. They are also called Niemann–Pick disease cells or NPD cells. These histiocytic cells are about 30–70  $\mu\text{M}$  in diameter and the cytoplasm is chock full with lipid droplets that have a mulberry-like appearance. NP-A brains are firm, with a reduced weight and a shrunken cerebellum and to a lesser extent, the cerebrum. Glial cells and foam cells are laden with lipid and are common around blood vessels. Neurons, when found, are swollen and there is a drastic loss of myelin. The spinal cord and deep nuclei may show similar changes. Peripheral nerves can be severely affected with the loss of both myelin and inclusion bodies in Schwann cells. Visceral involvement is severe in the BM and then the spleen, which can be enlarged up to 10 times its original size. Lymph nodes, liver, and kidneys are often affected. Lung pathology is prominent, particularly in NP-B cases. They are increased in size and foam cells invade vessels, interlobular septae, pleura, and even accumulate within the alveolar spaces (149,154,156). In the liver, the sinusoids are filled with numerous Kupffer cells or macrophages with abundant clear and vacuolar cytoplasm (Niemann–Pick cells). Hepatocytes are swollen with pale cytoplasm, suggesting an accumulation of lipid substances. The liver also shows varying degrees of fibrosis with focal regenerative proliferation of hepatocytes. In the spleen, the red pulps are infiltrated with numerous Niemann–Pick cells and the white pulps are atrophic. In a case of myocardial dysfunction leading to death, autopsy revealed a flabby, enlarged heart with marked dilatation of the left ventricle due to atherosclerosis. In the atherosclerotic lesions, large numbers of foam cells accumulating great amounts of cholesteryl ester were present (154).

### 104.6.3 Biochemistry

ASM degrades sphingomyelin to ceramide and phosphorylcholine. NP-A and NP-B are characterized by abnormal accumulation of sphingomyelin in most tissues, secondary to ASM deficiency (157). The types and amounts of lipids stored in the RES and visceral organs are similar. The profile of lipids in the brain differs. In one study, there was an increase in sphingomyelin in extraneural tissues of both types. Lyso-sphingomyelin was elevated in the brain of two type A patients and was normal in the brain of one type B patient (4). These lyso-sphingolipids seem to be toxic metabolites in the brain of patients with sphingolipid storage diseases, and have been implicated in the pathogenesis of Niemann–Pick as well as other diseases such as Krabbe disease. Type A has extensive

accumulation of sphingomyelin up to 50-fold of normal values, representing 2–5% of total body weight (158). Bis-mono-acylglycero-phosphate increases up to 100-fold, and the level of cholesterol is also somewhat elevated. There are reports of accumulation of GSLs and glycolipids. These include glucocerebroside, GM2- and GM3-gangliosides. In addition, lesser accumulation of lactocylceramide, globotriaosylceramide, and globotetraocylceramide are reported in liver and spleen (159).

Patients with Niemann–Pick, type A, have ASM activity levels ranging from nondetectable to 5% of normal, when determined using cultured fibroblasts/leukocytes as the enzyme source (157,160,161). Similar findings have been reported in tissues, including liver and brain. ASM activity in cells or tissues from type B patients is more elevated than that from Niemann–Pick type A patients. When determined in cultured cells, residual enzyme activities range between 2 and 10% in Niemann–Pick, type B. It is also possible to measure sphingomyelin hydrolysis using cell-loading assays and fluorescently labeled C12-sphingomyelin (BODIPY-SM, Molecular Probes, Inc., Eugene, OR) as substrate. These cell-loading assays reveal a higher rate of sphingomyelin hydrolysis in cultured cells from type B patients. The enzyme assay is not helpful in ascertaining carriers due to the overlap in enzyme activities between normals and carriers. For a family with known mutations, it is best to screen for carriers using molecular DNA analysis. Prenatal diagnosis using measurement of ASM activity, amniocyte cell-loading studies, and/or DNA analysis is available and reliable.

Plasma chitotriosidase and the chemokine CCL18 may also serve as markers for the formation of pathological lipid-laden macrophages in type B NPD. In situations where the differential diagnosis is not obvious clinically, these markers may help narrow the differential diagnosis and are of assistance in identifying the most probable specific confirmatory enzyme assay in comparable populations of children with organomegaly (162,163).

In NPD, sphingosylphosphocholine (SPC, a sphingomyelin metabolite) accumulates in various tissues, including the brain, where it might act as a toxic stimulus, contributing to the development of neurological symptoms. Acute administration of SPC to astrocytes in culture promotes  $\text{Ca}^{++}$  responses and the release of glutamate that leads to cytosolic  $[\text{Ca}^{++}]$  elevation in neurons. Chronic stimulation by SPC leads astrocytes to proliferate, transforming them into an activated state contributing to the inflammatory response. Acute SPC stimulation causes activated astrocytes to release more glutamate. In conclusion, chronic and acute exposure to SPC constitute harmful signals that may have a role in the events leading to neurodegeneration. These new insights into the interplay between astrocytes and neurons offer new opportunities for therapeutic approaches in Niemann–Pick type A disease as well as in other neurodegenerative diseases (164).

### 104.6.4 Genetics

The human ASM (*hASM*) gene has been mapped to chromosome 11p15.1–15.4. Types A and B are allelic. Carrier frequency for NP-A in Ashkenazi Jewish is high at 1:80 individuals. More than 50 mutations are known for this disease of which three, R496I, I302 P, FSP330 (stop codon), account for 92% of all mutant alleles in Ashkenazi Jews. NP-A has been described in non-Jewish populations. NP-B is rare in the Ashkenazim. The R496I mutation has been found in some type B Ashkenazi Jewish patients on one of the alleles, with a different mutation on the other allele. One of these mutations, p.R608del, is found in NP type B patients of both Ashkenazi Jewish and north African background. In fact, this mutation accounts for 87% of alleles in NP-B patients from the Maghreb countries (Algeria, Morocco, and Tunisia). Cases with a form of protracted neuronopathic disease have been due to combinations of mutations that produce a greater deficiency in ASM than typical type B patients. NP phenotype–genotype correlations hold true for the common Ashkenazi Jewish mutations, yet often the identical combination of mutations in other populations does not predict a similar clinical phenotype or course. Frameshift mutations due to splicing, small and large insertions and deletions, and splicing defects with little or no residual ASM activity are called type A alleles. Missense and in-frame codon deletions and splicing mutations retaining significant residual activity (>5% of in vitro-expressed wild-type activity) are neuroprotective and are called type B alleles (55). Inheritance of two type A alleles predicts a type A phenotype with a neurodegenerative disease course. Inheritance of one type B allele is neuroprotective and predictive for a type B phenotype, even if the other allele is an A allele (165). The measurement of ASM activity in peripheral leukocytes or cultured skin fibroblasts is commonly used for the diagnosis of ASM-deficient NPD; however, falsely normal enzyme activity has been reported in some patients (11). Thus, DNA diagnosis plays an important role in accurate diagnosis. More than 100 mutations within the *SMPD1* gene causing ASM-deficient NPD are known (human gene mutation database: <http://www.hgmd.org/>). Functional changes in the protein resulting from some mutations have been characterized (105). According to demographic data, most reported cases of type A NPD occur in Ashkenazi Jews. Three common mutations comprise >90% of the mutant alleles in this ethnic population (166). In contrast, type B NPD is panethnic and genetically heterogeneous (55,167). Few mutations have been found with a relatively high frequency in specific populations. Mutation c.1823\_1825delGCC (p.R608del) is always associated with the type B phenotype. This mutation has a low frequency in Europe: 9.4% in Italy, the Czech Republic, and Slovakia. Reported frequencies of mutation p.R608del in type B NP-D patients were 9.4% in Italy, 12% in 324 patients

of multiethnic origin, 86.6% in northern Africa, and 100% in four patients from the Canary Islands. Mutations p.Y67C and p.A482E were associated with type A. The p.R608del-type B association is confirmed (168). Eight new mutations causing types A and B NPD in six unrelated patients were identified: c.631t>c (p.W211R), c.757g>c (p.D253H), c.1729A>G (p.H577R), c.940G>A (p.V314M), c.1280A>g (p.H427R), c.1564A>G (p.N522S), c.1657delACCGCCT (F5253), and c.1575G>C (p.Q525H (169). A novel allele c.1352C>A was recently reported in a Taiwanese (167). An exhaustive molecular analysis of 19 Spanish NMA/B patients and two from Maghreb was conducted. Ten of the detected mutations were novel. The most frequent mutations in the 21 NPD patients were c.1823\_1825delGCC (p.R608del) (38%) and c.1445C>A (p.A482E) (9%). The mutations p.W168X, p.Y313X, p.F390del, p.Y467S, p.A482E and p.T592del found in the homozygous state were associated with type A disease. The same correlation was established for mutations p.G245S, p.Y367C and p.H421R, found in compound heterozygotes. The p.R608del accounted for 61.5% of mutant alleles in the type B subgroup of patients (168). The mutations, L137P, SSP189, and I549P comprise more than 70% of all mutations in Turkish patients with NPD type B. A novel mutation R505G has been recently described in a patient presenting with epigastric pain and hepatosplenomegaly (170).

### 104.6.5 Animal Models

Two mouse models of NP disease types A and B have been constructed by gene-targeting strategies. The NP disease “knockouts” were normal until about 3 months of age when progressive ataxia developed and death was around 7 months (171–173).

### 104.6.6 Treatment

BMT has failed for NP-A. There is, however, room for its use in NP-B patients. Similar results were obtained with preclinical testing of enzyme replacement in mouse models. Again, enzyme replacement is unlikely to work for NP-A due to the impenetrability of the BBB. Hematopoietic stem cell-mediated gene therapy also holds promise for treatment of NP-B, but not NP-A. Studies in mouse models have shown little or no improvement in the CNS.

Cloned mouse NSCs or human NSCs were injected into CNS sites in high concentrations into neonatal ASM knockout mice, and into 10 wild-type mice. Noninjected ASM controls had developed widespread neuronal and glial vacuolation and lysosomal accumulation of sphingomyelin and cholesterol when examined histologically at 16 weeks of age. At 16 weeks, NSC-injected mice showed a dramatic decrease in neuronal and glial vacuolation and in cholesterol accumulation throughout the cerebral neocortex, hippocampal formation, striatum,

and cerebellum, with lesser but clear improvement throughout the brainstem. Loss of Purkinje neurons and decline in rotarod performance were still present in injected ASM mice. Stem cells may not distribute widely enough within the CNS to produce optimal therapeutic results in the large human brain, even at the high-injection dosage of stem cells used. Also, long-term effects are unknown, mouse experiments being limited to months rather than to years (174).

Gene therapy has been intensively investigated with AAV being the most widely accepted among several vehicles for *in vivo* targeting of nondividing cells in the CNS. This approach has been effective in the ASM mouse model (174).

Gene therapy with a retroviral vector encoding for hASM in deficient mice has been explored (175). Miranda et al. transplanted newborn ASM-deficient mice and found higher levels of ASM activity in the white blood cells compared with untreated litter mates. In addition, levels of ASM activity in the spleen, liver, and lung were higher than untreated animals; however, levels in the brain remained low, similar to those not receiving a BM transplant. These levels correlated with decreases of sphingomyelin deposition in the spleen, liver, and lung. Animals undergoing transplant survived longer than those not treated, but developed ataxia, weight loss, and eventually died. None of these therapies are recommended for NP (166,176,177).

Intracerebroventricular (ICV) delivery of recombinant hASM into ASM mice is effective. ICV delivery of enzyme leads to distribution of the hydrolase throughout the CNS. A significant reduction in lysosomal accumulation of sphingomyelin is observed throughout the brain, spinal cord and viscera. Repeated ICV infusions of ASM are effective at improving the disease phenotype in the ASM mouse as indicated by reduced SPM accumulation within the CNS and partial alleviation of motor abnormalities (178).

Direct intraparenchymal brain injections of purified recombinant hASM corrects the storage pathology in a mouse model of NPD-A (ASMKO). Immunohistochemical analysis after 1 week indicated that animals treated with greater than 1 µg hASM/site showed detectable levels of enzyme around the injected regions. Localized clearance of sphingomyelin and cholesterol storage was observed in animals that administered lower doses of enzyme, starting at 100 ng hASM/site. Areas of correction were noted at distal sites such as in the contralateral hemispheres. Indications of storage reaccumulation were seen after 2 weeks postinjection. Injections of hASM did not cause any significant cell infiltration, astrogliosis, or microglial activation. Intraparenchymal injection of hASM is associated with minimal toxicity and can lead to regional reductions in storage pathology in the ASMKO mouse. They were safe and effective at correcting the lysosomal storage pathology. The extent of correction achieved in the vicinity of the injection site was

substantial for mouse brain, but needs to be significantly improved in order to treat a larger brain. Repeated administration every 2–3 weeks would be necessary to maintain the correction of lysosomal storage pathology. Achieving global distribution of the enzyme and long-term reversal of storage pathology in a larger brain will require further optimization of the route of delivery and methods for repeated infusions into the brain (179).

A new delivery vehicle for ERT of type B NPD consists of polystyrene and poly(lactic-coglycolic) acid polymer nanocarriers targeted to intercellular adhesion molecule (ICAM)-1, an endothelial surface protein upregulated in type B NPD. ICAM-1-targeted nanocarriers enhance the ERT for type B NPD. ICAM-1 targeting provides a means to enhance the delivery of recombinant ASM to vascular endothelium. Anti-ICAM particle formulations achieved improved pulmonary uptake compared with the naked enzyme, providing a means to enhance enzyme delivery to this critical type B NPD target organ (180).

In one 18-month-old with NP type B who underwent two allogeneic hematopoietic progenitor cell (HPC) transplants from her HLA-identical sister, engraftment was durable, with the normalization of sphingomyelinase. Normal BM, hepatic and pulmonary functions were regained. At 13 years of age, the patient was able to perform activities of daily living without assistance and attend school full time, in spite of extensive graft versus host disease (GVHD) and extremity contractures as transplant complications. Two others had less clear cut benefits with continued neurological deterioration in one case transplanted at age 3.5 years, and another with the resolution of pulmonary symptoms but continued hepatomegaly and neurocognitive decline (22,171,177,181).

A prenatally diagnosed girl with NPD type A underwent cord blood stem cell transplantation at 3 months of age. She was neurologically intact at the time of transplant. There were severe neurologic and visceral complications several months following transplant (182). Transplantation may be considered for those with severe disease, especially pulmonary symptoms. Successful hematopoietic stem cell transplantation (HSCT) for NPD type B is reported to improve the patient's pulmonary symptoms, with the caveat of graft versus host disease and other complications (183).

In general, patients with NP type B disease have not received transplant as definitive therapy because of the lower incidences of neurologic sequelae. HPC transplantation for patients with NP type B disease is feasible and potentially beneficial when performed prior to the onset of severe pulmonary and liver diseases. Given the serious potential sequelae of NP type B disease, HPC transplant should be considered in patients with severe visceral complications (177). Future directions should be directed toward ERT or gene therapy, which would solve the problem of unsuitable donors, thus reducing the complications of transplant.

## 104.7 NIEMANN–PICK DISEASE, TYPES C AND D

### 104.7.1 Clinical Presentation

Age of presentation is variable from the perinatal period to adulthood. Initial manifestations can be neurologic, hepatic, or psychiatric. The courses of systemic and neurologic disease are independent. Liver involvement is often present in the first month of life. Hepatosplenomegaly is a common finding, but may be absent in 15% of patients. The most frequent form begins in childhood with ataxia, vertical supranuclear palsy, and psychomotor regression. Dysarthria, dystonia, cataplexy, tremors, Parkinsonism seizures, jaundice, and hepatosplenomegaly can also be present. There is variability in clinical presentation, with patients developing clinical signs in their second, third, fifth, or sixth decades. The subacute form of NP-C1 (previously known as NP-D) described in French Canadians of Acadian descent seems to have a more homogeneous phenotype. It is presumed that all these patients were traced to a small set of common ancestors who immigrated to Nova Scotia from France and have a similar genetic defect. Other variants include an acute form with hydrops, an early form with neonatal hepatitis, and a slow chronic form with progressive neurologic deterioration with patients surviving into adulthood. An early lethal form of NP-C has been reported in three patients with severe pulmonary involvement (184,185). Gingival enlargement has been reported in a patient with NPD (186).

Antenatal presentation of NPC disease is most often correlated with a severe and rapidly fatal form of the disease. Sonographic signs consist of fetal ascites with hypoferritinemia, with or without hepatosplenomegaly. Prenatal diagnosis is possible using AF and/or ascites fluid samples, preceded by fetal blood screening for high chitotriosidase levels. Poor prognosis during the perinatal period correlates with hepatocellular insufficiency. In siblings with NP-C disease, the infant may develop a prenatal or neonatal form of variable severity and evolution, independent of the type of mutation, highlighting the complexity of genetic counseling for this disorder (187). Prenatal onset may be detected antenatally by congenital thrombocytopenia, congenital anemia, petechial rash, cholestasis and hepatomegaly immediately after birth (188).

Psychiatric signs and cognitive troubles constitute the most frequent symptoms in adults and may appear after 50 years. Main clinical features include vertical supranuclear gaze palsy, cerebellar ataxia, dysarthria, cognitive decline and movement disorders. Recognizing mild vertical supranuclear gaze palsy is a valuable clue to the diagnosis as it is a constant and specific feature (189). Early nonspecific signs result in an average delay in diagnosis of 6.2 years (181). This is particularly true for psychiatric symptoms (190). A patient with bipolar disorder in adolescence was recently reported (191). Whilst postictal

psychosis is rarely reported prior to 16 years, NPC may increase the risk for postictal psychosis in the pediatric population (192). Cataplexy and cortical myoclonus rarely do occur as the main symptoms of NPC and severely impair motor performance (193). NPC cases with cataplexy demonstrate low levels of CSF hypocretin-1 (194). Very rarely, NPD type C may present with purely visceral disease without neurological symptoms. Therefore, NPD type C should be considered in differential diagnosis of isolated hepatosplenomegaly with foam cells in adulthood (195). The rare type C2 almost uniformly presents with respiratory distress in early infancy. Pulmonary alveolar proteinosis due to NP-C2 disease should be considered in cases of infants with respiratory symptoms of bronchiolitis or pneumonia not responding to common treatments (196).

### 104.7.2 Diagnosis

Diagnosis of NPC requires a high index of suspicion and should be considered in a patient with hepatosplenomegaly with or without neurodevelopmental signs. The initial presentation in a pediatric patient may be restricted to isolated hepatomegaly, splenomegaly, or both. When neurological symptoms are absent, one may confuse this entity with NPD type B or GD type II. Decreased activity of acid  $\beta$ -glucosidase in leukocytes and elevated serum chitotriosidase are present; however, fibroblast  $\beta$ -glucosidase will be normal. Cholesterol esterification assays in cultured skin fibroblasts and NPC gene analysis always leads to the correct diagnosis of NPC. Therefore, diagnostic delay may occur in NPC due to false positive testing for Gaucher disease (GD) (197). Denaturing high-performance liquid chromatography is a rapid, low-cost, highly accurate, and efficient technique for the detection of NPC genetic variants and mutations (198). BM aspirates are not reliable as a screening test in the diagnosis of NPC presenting with hepatomegaly. While a positive result is helpful, a negative result cannot exclude the diagnosis. Skin biopsy for fibroblast culture enables definitive tests to be performed (199). Voxel-based morphometry of T1-weighted images and tract-based spatial statistics of diffusion tensor images demonstrate reduction in gray matter and white matter tracts due to impaired myelination and altered axonal structure. Volumetric analysis of gray matter and diffusion tensor imaging (DTI) may be useful modalities for indexing illness stage and monitoring the response to emerging treatment (200). Ocular motor measures provide an index of disease severity and may be a useful adjunct for monitoring illness progress and medication response (201). Differing aspects of tremor, Parkinsonism, ataxia, and dystonia are quantifiable in NPC patients through spiral analysis, which is a computerized method of analyzing upper limb motor physiology. This may serve as ancillary measures of NP-C pathophysiology, allowing for the objective evaluation of new therapies (202).

### 104.7.3 Pathology

While the precise cause of neurodegeneration in NP-C remains unclear, it is clear that defects in either NP-C1 or NP-C2 protein cause a “traffic jam” of lipids in the late endosome (203,204).

Foam cells are found in many tissues. Sea-blue histiocytes are seen in the BM with Giemsa–Wright stains. Such cells are not specific for NP-C and may be absent in cases without enlarged organs. Characteristic inclusions may be identified in skin. Neuronal storage, swollen perikarya, and cytoplasmic ballooning with pleomorphic, electron-dense inclusions are found in neurons and other cells throughout the nervous system. Apoptosis of neurons and Purkinje cells in the cerebellum are prominent. Meganeurites reminiscent of the ones seen in GM2-gangliosidosis are present. Axonal spheroids in the thalamus may be present.

In NPD C2, lung involvement is universal. Histology shows typical signs of pulmonary alveolar lipoproteinosis with an abnormal intra-alveolar accumulation of surfactant rich in cholesterol, invasion of macrophages, and hyperplasia of the alveolar cells (196,205).

### 104.7.4 Biochemistry

The metabolic basis of NPD, types C (1 and 2) and D was not fully elucidated until fairly recently. In fact, NP-D and NP-C1 are allelic variants due to defects in the same gene (see “Genetics” section). They have been reclassified as cellular lipid trafficking disorders, following several studies by Pentchev in the early 1980s (206,207). Type D refers to a genetic isolate from Nova Scotia (208). ASM is elevated or normal in leukocytes and tissues of NP-C patients (209,210). Cultured fibroblasts, however, show a decrease in exogenous sphingomyelin degradation (157,211,212) and ASM activity. The decrease in ASM activity in NP-C fibroblasts has been attributed to excessive sequestration of cholesterol. GM2-ganglioside accumulates in lysosomes of cultured cells from patients, even though hexosaminidase A activity is normal (213). The reason for this may be impaired cellular transport of GM2-ganglioside (214,215). There is also a many-fold elevation of free sphingoid long-chain bases in tissues and cultured cells (216). The primary biochemical defect in NP-C is aberrant intracellular transport of endocytosed cholesterol (203,217). The internalization, transport to endocytic vesicles, and hydrolysis of LDL is normal, yet further transport of unesterified cholesterol is impaired. Hence, there is the accumulation of unesterified cholesterol in the late endosome/lysosomal compartments with subsequent failure to induce all LDL-mediated homeostatic responses (218). In NP-C1 cells, LDL cholesterol traffics directly to lysosomes through endosomes, bypassing the plasma membrane and becoming entrapped. The function of NP-C1 protein is presumably the transport of LDL to PM (219). NP-C1 protein is necessary for the distribution of PM-derived cholesterol (220).

Recent studies have established that NPC is associated with an induction of autophagy in human fibroblasts and in mice. Autophagy is a regulated and evolutionarily conserved process by which cytoplasmic proteins are sequestered within autophagosomes and targeted for degradation. This pathway enables recycling of damaged macromolecules to promote cell survival and in other instances, autophagy leads to cell stress and programmed cell death. Autophagy is evidenced by the presence of autophagic vacuole-like structures, and increases in autophagic activity are associated with alteration in lysosomal function and protein ubiquitination (221,222). Cholesterol accumulation can have a detrimental effect on phagosome maturation by impairing the activation of Rab7 leading to failure of the Niemann–Pick type C phagosomes to fuse with lysosomes (223).

Autophagy induction and flux are increased in NP-C by signaling through the class III PI3K/Beclin-1 complex, which is critical for the formation of autophagosomes (224,225). Determining the role of autophagy in NP-C pathogenesis is an important task since targeting this pathway is a potential therapeutic strategy for treating this incurable disease. Hyperphosphorylation and the aggregation of the microtubule-binding protein tau characterize a diverse array of neurodegenerative disorders (226). NPC1/tau double-null mouse mutants exhibit an exacerbated NP-C phenotype, including severe systemic manifestations, and die significantly earlier than NP-C1 single-null mutants. Acute reductions of tau in NP-C1-deficient fibroblasts significantly decrease autophagic induction and flux, while having no effect on the autophagic pathway in control cells. Tau’s normal function is critical to the induction of autophagy in NP-C1 deficiency (227). Increased oxidative stress may be a contributing factor to the pathology of NP-C (228).

NP-C1 deficiency leads to cell autonomous, selective neurodegeneration. Ataxic symptoms of NP-C disease may arise from Purkinje cell death rather than cellular dysfunction (229). Neurodegeneration of *Npc1*<sup>−/−</sup> mice is greatly affected by the loss/dysfunction of fibrillary astrocytes (230). Estradiol treatment may be useful in ameliorating the progression of the disease (231).

Wild-type RID- $\alpha$  rescues lipid-sorting defects in cells from patients with this disease by a mechanism involving a class III phosphatidylinositol-3-kinase. In contrast to NP-C disease gene products that are localized to late endosomes/lysosomes, RID- $\alpha$  induces the accumulation of autophagy-like vesicles with a unique molecular composition. Ectopic RID- $\alpha$  regulates intracellular cholesterol trafficking at two distinct levels: the egress from endosomes and transport to the ER necessary for homeostatic gene regulation. RID- $\alpha$  also induces a novel cellular phenotype, suggesting that it activates an autonomous cholesterol regulatory mechanism distinct from NPC disease gene products (232). The presence of neurofibrillary tangles (NFT) in the hippocampus of a 4-year-old NP-C patient suggests that NFTs are not

aging dependent. Activation of cdc2/cyclin B kinase and downstream mitotic indices are associated with NFT formation, signifying the contribution of abortive cell cycle to neurodegeneration. Cdc2 inhibitors may be therapeutically used for the early intervention of neurodegeneration and NFT formation in NPC (233).

A cholesterol-binding protein, AnxA6, is an important molecule regulating the organization of lysosome-like structures responsible for the abnormal accumulation of cholesterol and GSLs in NP-C fibroblasts. Annexin A6 may participate in the formation of cholesterol-rich lipid raft (LR) platforms in late endosomes contributing to the pathology of NP-C disease (234). Defects in synaptic transmission at glutamatergic and GABAergic synapses may result in part from the impairment of synaptic vesicle trafficking contributing to progressive neurological impairments in NP-C disease (235,236). Enhanced excitatory synaptic transmission and decreased synaptic plasticity due to decreased adenosine release may contribute to seizures, neurodegeneration, and dementia in NP-C (237).

Sphingosine storage in NP-C1 disease pathogenesis leads to altered calcium homeostasis and the secondary storage of sphingolipids and cholesterol. This may explain the block in late endosome-to-lysosome transport in NP-C disease, resulting in downstream storage of cholesterol and GSLs (238). The presence of lysosomal phospholipid lyso-bisphosphatidic acid (LBPA) in the lysosome may be important for NP-C2-membrane interactions, suggesting an important role for LBPA in NP-C2-mediated cholesterol trafficking (58).

Decreased activity of acid  $\beta$ -glucosidase, elevated serum chitotriosidase, and tartrate-resistant acid phosphatase led to an initial diagnosis of GD in a patient. The failure to respond to ERT after 1 year put the diagnosis in question. Cholesterol esterification assays in cultured skin fibroblasts and gene analysis led to the correct diagnosis of NPC. The patient had markedly reduced cholesterol esterification and was a compound heterozygote for known and novel mutations in the *NPC* gene (395delC and 2068insTCCC), which predict a truncated protein. Acid  $\beta$ -glucosidase activity was in the normal range in skin fibroblasts. Therefore, diagnostic delay may occur in NP-C due to false positive testing for GD (197).

Loss of NP-C1 function alters TG metabolism in murine hepatocytes by increasing the metabolic flux of carbons into cholesterol synthesis. There is evidence that the *NPC1* genotype contributes to serum TG levels in humans, which is consistent with the observation that TG levels are increased in a subset of patients with NP-C1. In a genome-wide association study, the *NPC1* locus was detected as a risk locus for morbid obesity. Based on the recent literature (75,141,176), the *NPC1* gene is emerging as a player in TG metabolism and obesity (239).

Early endocytic defects impact NP-C disease and such heterogeneity in NP-C disease results in diverse responses to therapeutic interventions aimed at modulating the trafficking of lipids. The nucleotide cycling

or cellular knockdown of the small GTP-binding protein, ARF6, markedly impacts cholesterol homeostasis. Unregulated ARF6 activation attenuates the NPC phenotype by decreasing cholesterol accumulation and restoring normal sphingolipid trafficking (240). Cell death in the brain of NP-C disease occurs through apoptosis and is mediated by the TNF receptor superfamily pathway (241). Degeneration of cultured NPC1-like cortical neurons can be attenuated by the inhibition of cathepsin B or D enzyme activity. This suggests that the modulation of activity and subcellular distribution of cathepsins may impact neuronal vulnerability in *Npc1*<sup>-/-</sup> brains. Their inhibitors may have therapeutic potential in attenuating NP-C pathology (242). Apoptosis via activation of the c-Abl/p73 pathway is an early process in cerebellar neuronal death in NP-C mice. Inhibition of c-Abl treats the neurodegeneration of Purkinje neurons and ameliorates neurological symptoms in NP-C mice (243).

Studies have demonstrated that a lack of synthesis of the neurosteroid allopregnanolone in the early neonatal period may contribute to neuropathology in NP-C mice. Treatment studies suggest that allopregnanolone may function in the early postnatal period in the brain of mice, and may be related to cellular development, proliferation, and migration. Injection of allopregnanolone in *Npc1*<sup>-/-</sup> mice reduces cholesterol accumulation, improves autophagic and lysosomal function, enhances myelination, and reduces inflammation (244). The mechanism(s) through which allopregnanolone functions in NP-C is unknown. Allopregnanolone can mediate beneficial actions in cultured Purkinje neurons, which are mediated through GABAA-receptors (245).

NPC1 human skin fibroblasts overexpressing endosomal Rab proteins (Rab7 or Rab9) show a correction in the storage disease phenotype. Recombinant human Rab9 fused with herpes simplex virus VP22 protein fragment was overexpressed, purified, and added to the culture medium to induce protein transduction. VP22-Rab9 transduction into NPC1 fibroblasts led to significant reduction in cellular free cholesterol levels with no cytotoxicity. The reduction in cellular free cholesterol levels was associated with the correction of abnormal intracellular trafficking of BODIPY-lactosylceramide and an increase of sterols in the culture media. The clearance of lysosomal-free cholesterol was also associated with a decrease in LDL-receptor levels. In addition, the reduction of intracellular cholesterol by VP22-Rab9 transduction in NP-C2 fibroblasts and in NP-C1 neurons of cultured mouse was demonstrated, as well as the correction of membrane traffic suggesting this could be a novel therapeutic approach (246).

### 104.7.5 Genetics

NPD type C is panethnic. Approximately 95% of patients have mutations in the *NP-C1* gene mapped at 18q11 (56kb, 25 exons). The remainder have mutations in the

*NP-C2* gene, which maps to 14q24.3 (13.5kb, 5 exons). *NP-C1* encodes a 1278 amino acid integral membrane protein with 13 transmembrane domains, one cytoplasmic loop, three large luminal hydrophilic loops, a luminal amino terminus, and a cytoplasmic tail with a dileucine motif (247). More than 243 different loss-of-function mutations of *NPC1* have been reported (75), in addition to 60 different non-disease-causing polymorphisms (105,248). These mutations are scattered through the *NP-C1* gene and affect all functional domains with the exception of the leucine zipper motif (luminal amino terminus). Three frequent mutations have been described. Meaningful genotype and clinical phenotype associations are difficult, primarily due to the fact that most *NP-C1* patients are compound heterozygous for different mutations, yet some associations have been established. For *NP-C1* patients with homozygous mutations, the relatively common I1061T mutation, present in ~20% of all known mutations for *NPC1* and prominent among individuals of western European descent, predisposes patients to the classic *NP-C1* clinical phenotype (249–251). It is highly prevalent in a Spanish American isolate in southern Colorado and New Mexico (37). P1007A is the second most frequent mutation in Europe. G992W is typical of Nova Scotian patients and rare in other populations. Some mutations are prevalent only in Japanese (R518Q) (185) or in Italian patients (P474L) (252). Molecular analysis of the *NP-C1* gene is problematic because of the size of the gene, the large number of private mutations, and the occurrence of numerous polymorphisms. Report of the National Niemann–Pick Type C1 Disease Database found (1) a significantly decreased concentration of plasma LDL cholesterol and increased plasma TGs in the majority of *NP C1* disease patients, (2) a significantly decreased concentration of HDL cholesterol for all patient groups that were not associated with the concentration of plasma TGs, (3) a significant inverse association between the concentration of HDL cholesterol and biochemical phenotype and HDL cholesterol and the age of death for *NPC1* patients, and (4) five previously unreported disease-causing mutations in *NPC1* (Y628C, P887L, I923V, A1151T, and 3741\_3744delACTC). The results indicate the presence of a unique *NP-C1*-related dyslipidemia characterized by hypoalphalipoproteinemia, which may serve as a valuable and convenient biomarker of the biochemical severity of the disease, in addition to monitoring the potential benefit of therapies used for the eventual treatment of *NPC* disease. The following are severe novel mutations (c.2792\_3delAG and c.1437\_42delCACCAT, and c.1241\_2delTC), as are previously reported mutations c.2279\_81delTCT, p.T1205K, and p.L1213V that correlate with a severe phenotype (188). Two novel sequence variants, c.1997G>A (S666N) and c.2882A>G (N961S), in the *NPC1* gene account for a purely visceral form of *NP-C* in adults. *NP-C1* deficiency results in abnormal expression of genes involved in steroid synthesis and cholesterol transport and cell adhesion,

which could be responsible for neuroinflammation and hypomyelination. Dysregulated genes from microarray data, some validated, represent genes belonging to classic immune pathways (e.g. B cell receptor signaling pathway) in cerebellar pathogenesis in *Npc1*<sup>–/–</sup> mice. Based on these results, treatments targeting cell adhesion and/or immune responses combined with the facilitation of cholesterol egress from late endosomes/lysosomes have been proposed (253).

The *HE1* or *NP-C2* gene was identified using a proteomic approach to characterize soluble lysosomal proteins (254). The 130-aa *NP-C2* protein was previously characterized (255) as a major secretory protein present in mammalian epididymis and functions as a cholesterol-transfer protein. Porcine *NP-C2* binds cholesterol with 1:1 stoichiometry. Potential physiological functions of *NP-C2* include preventing inappropriate sterol intercalation into the lysosomal membrane, presentation of sterol to a membrane-bound transporter such as *NP-C1*, or some other regulatory or enzymatic activity. It was found mutated in *NP-C2* patients. Only a few cases are known to date. Nearly all have nonsense or frameshift mutations. The E20X mutation accounts for nearly half of the mutant alleles published. Only 13 different disease-causing mutations have been described for *NP-C2*. Functional characterization of mutant proteins shows good genotype–phenotype correlation for some of the mutations described (264–266). These mutations are c.133C4T, c.141C4A, and c.295T4C, a mutant carrying two in cis mutations, (p.E1188fsX54, and p.T1205NfsX53). An intronic c.464-2A>C change at the 3' acceptor splice site of intron 4 affected *NP-C1* messenger RNA processing, as well as a *NP-C2* mutant caused by a change of the first codon (p.M1L) have been described (265).

Six novel mutations were recently reported in Taiwanese/Chinese patients (N968S, G1015V, G1034R, V1212L, S738Stop, and I635fs) (266). A novel point mutation c.1554-1009G>A has also been recently reported in a Spanish patient (13). Specific diagnosis of *NP-C* is best achieved by filipin staining of cultured fibroblasts grown in the presence of LDL. Filipin binds to the excess unesterified cholesterol and appears as dense birefringent granules in the cytoplasm. Estimation of the degree of impaired LDL-induced cholesterol esterification identifies 80% of patients. Filipin staining is the more sensitive, cheaper, and easier test.

### 104.7.6 Animal Models

Pentchev et al. (142) described a strain of BALB/C mice with many of the characteristics of *NP* disease. These mice exhibited reduced ASM activity and elevated levels of sphingomyelin and cholesterol. An independent strain of C57BLKS/J mice with similar biochemical and clinical findings of ataxia and premature death was described (255). The ASM gene was sequenced from both strains of mice, and no molecular abnormalities were identified

(172). These are naturally occurring mouse models for NP-C1 disease.

Current mouse models of NP-C are not well suited for studying liver disease due to rapidly progressing neurological disease. To facilitate the study of NP-C-associated liver dysfunction, novel mouse models have been developed using antisense oligonucleotides to ablate NP-C1 expression primarily in the liver. NP-C1 knockdown leads to a liver disease phenotype similar to that of patients with NP-C and the NP-Cnih mouse model (267).

NP-C knockout models in the nematode *Caenorhabditis elegans* are available to study human disease (268). Also, an NP-C disease model has been established through the mutation of *Drosophila* NP-C1a (*dnp1a*). Loss of dNP-C1a caused profound changes in cholesterol distribution and thus disrupted LRs resulting in disease mimicking the human form (269).

In *Saccharomyces cerevisiae*, a homolog of the human NP-C1 protein encoded by the *NCR1* gene is Ncr1p. It localizes to the vacuole, the yeast equivalent of the mammalian endosome-lysosome system. Deletion of *NCR1* from the yeast genome results in resistance to the ether lipid drug, edelfosine. Results indicate that edelfosine has a cytotoxic, rather than cytostatic, effect on wild-type yeast cells. One amino acid change that severely compromises Ncr1p function as assessed using the edelfosine resistance assay established *S. cerevisiae* as a model system that can be exploited to analyze the molecular consequences of patient mutations in NPC1 (270).

The yeast homolog of human NP-C2, *S. cerevisiae* Npc2p, is evolutionarily related to mammalian NP-C2 proteins. Through colocalization, subcellular fractionation, and secretion analyses, yeast Npc2p is similar to human NP-C2 when expressed in mammalian cells. It can efficiently correct unesterified cholesterol and GM1 accumulation in *hNPC2*<sup>-/-</sup> fibroblasts demonstrating it is a functional homolog of human NP-C2. The yeast genome encodes functional homolog of hNP-C1 (11,248) and hNP-C2 (271).

### 104.7.7 Treatment

Treatment is primarily supportive and includes anticonvulsants for the treatment of seizures and protriptyline in the treatment of cataplexy. SSRIs are effective for cataplexy, but at higher doses than those usually used for depression (75,141,262,263,272,273). Mood stabilizers in some of the chronic later onset patients are beneficial. A multidisciplinary approach involving physical therapy, speech therapy, neurology, and nutritionists has been useful. Cholesterol-lowering drugs have been tried, and although tissue stores of cholesterol go down with therapy, there was no impact on the neurological deterioration or progression of this neurodegenerative disorder. Liver and BMT have failed to alter the course of this

disease as well. Several therapies have shown efficacy in the feline and mouse models of NP-C including miglustat, antioxidants, and pregnane X receptor (PXR) activators (member of the nuclear receptor superfamily of proteins that modulate the expression of genes involved in the clearance of structurally diverse endogenous and exogenous compounds) cyclodextrin and allopregnanolone alone or in combination with a drug that activates PXR.

Experts agree that the stabilization of neurological disease is the best attainable therapeutic goal in patients diagnosed with NP-C due to the fact that the irreversible damage or loss of neurons will likely already have occurred by the time the diagnosis of NP-C is made (274). With the recent approval of miglustat (275) and the possible development of additional disease-specific therapies (22,276), treatment can be aimed toward stabilizing neurological disease (277).

### 104.7.8 Approved Therapies

SRT represents a potential strategy for treatment. Very recently, SRT using miglustat has been approved in Europe for treating NPC (278). Miglustat, a small iminosugar, is a reversible inhibitor of the enzyme glucosylceramide synthase, which catalyzes the first step in the biosynthesis of most GSLs. Miglustat has pharmacokinetic properties that allow it to cross the BBB, making it a potential therapeutic agent for treating neurological symptoms in NPC patients.

The efficacy, safety, and tolerability of miglustat in juvenile, adult, and pediatric patients with NP-C have been demonstrated in clinical trials (181,273,279,280) and observational studies, (88,281–283), supported by findings from off-label use (284–286), preclinical studies (24,287,288), case reports (31,68,145,261,273,274,289–292), and the miglustat postauthorization surveillance program (274,293). Miglustat stabilized neurological disease progression in pediatric patients with comparable safety and tolerability to that observed in adults and juveniles. Age at diagnosis influenced response to treatment, and clinical benefit or slowing of disease progression was also seen in the earliest childhood forms (294). Findings demonstrate clinically beneficial effects of miglustat on neurological disease progression in adult, juvenile, and pediatric patients, particularly in those diagnosed in late childhood (6–11 years) and juveniles and adults 12 years and older, compared with those younger than 6 years (22,262,263,274,295). The safety/tolerability of miglustat in children was consistent with that observed in adult and juvenile NP-C patients (259). Tremors, diarrhea, flatulence, abdominal pain, and weight loss were frequently reported adverse events (181,273,291,296).

Decisions to treat NP-C patients with miglustat should be guided by a scheme included in consensus recommendations. Patient disease course and response to therapy should be followed up regularly (every 6–12 months)

based on investigations and the NP-C functional disability scale considered a useful measure. There are no reliable, validated biochemical markers of neurological disease progression. Imaging techniques have potential, but further evaluation is required (80,203,204,277,297).

Cyclodextrins (CDs) can sequester lipids in the hydrophobic core of their cup-like structure, enabling them to bind and traffic cholesterol away from cell bodies (22,175,298). In vitro studies have demonstrated that methyl- $\beta$ -cyclodextrin is more potent than hydroxypropyl- $\beta$ -cyclodextrin in reducing cholesterol and bis(monoacylglycerol) phosphate accumulation in NP-C-mutant fibroblasts. Brief treatment of cells with CDs causes an increase in cholesterol esterification by acyl CoA: cholesterol acyl transferase indicating increased cholesterol delivery to the ER. These findings suggest that cyclodextrin-mediated enhanced cholesterol transport from the endocytic system can reduce cholesterol accumulation in cells with defects in either NP-C1 or NP-C2 (299,300).

A derivative of  $\beta$ -cyclodextrin, 2-hydroxypropyl- $\beta$ -cyclodextrin (HP- $\beta$ -CD) is a promising experimental therapy for NPD type C. Several studies in mice have shown that it is capable of overcoming the block in cholesterol delivery to the ER allowing the sequestered sterol to be excreted from the body as bile acid. Liberated cholesterol flows into the cytosolic ester pool, suppresses sterol synthesis, downregulates SREBP2 and its target genes, and reduces the expression of macrophage-associated inflammatory genes (175,301,302). Treatment with CD delayed clinical disease onset, reduced intraneuronal storage and secondary markers of neurodegeneration, and significantly increased the life span of both Npc12/2 and Npc22/2 mice (303). Studies of the efficacy of HP- $\beta$ -CD in feline model of NP-C disease recognized a dose-dependent increase in hearing threshold associated with therapy as determined by brainstem auditory evoked response (BAER) testing (304). HP- $\beta$ -CD has been approved by the Food and Drug Administration (FDA) for the treatment of NP-C disease (176,298).

### 104.7.9 Experimental Therapeutics

Targeting inflammation in the brain represents a potential clinical intervention strategy that aims to slow the rate of disease progression and improve the quality of life. Non-steroidal anti-inflammatory drugs (NSAIDs) significantly prolonged the life span of NP-C1 mice and slowed the onset of clinical signs. Combining NSAID therapy with SRT resulted in additive benefit in murine models, whereas the antioxidant therapy was of no value (278).

ASM activity defects in fibroblasts from NP-C1 patients were corrected by sphingomyelin phosphodiesterase-1 (SMPD1) transfection or sphingomyelinase enzyme replacement. Both treatments resulted in a dramatic reduction in lysosomal cholesterol in fibroblasts (305).

In vitro studies have shown that the overexpression of certain Rab GTPases corrects defective membrane trafficking and reduces lipid storage in cultured NP-C fibroblasts. Rab9 overexpression has the potential to reduce stored lipids and prolong life span in vivo using a murine model of NP-C. Histological studies and lipid analysis of brain sections indicate that NP-C mice carrying the Rab9 transgene had dramatically reduced the storage of GM2- and GM3-gangliosides relative to NP-C animals lacking the transgene (306).

Currently, there are no proper evidence-based trials showing efficacy in humans using stem cell therapy in NP-C disease. Studies in mice suggest that neural stem cell NSC transplantation may have therapeutic effects. It protects Purkinje neurons without significant immunological response (307). Bone marrow-derived stem cells (BMDSCs) are able to promote neuronal network formation with functional synaptic transmission after transplantation into NP-C mouse cerebellum. The transplantation of BMDSCs reduces the inflammatory response by suppressing astroglial and microglial activation in a murine model of NP-C (308,309). Adipose tissue-derived stem cells (ADSCs) can rescue imperiled Purkinje neurons and alleviate the inflammatory response in NP-C disease mice (310).

## 104.8 FARBER'S DISEASE

### 104.8.1 Introduction

Farber's disease is a rare disorder caused by defects in acid ceramidase (aCDase), the lysosomal enzyme that breaks down sphingomyelin-derived ceramide, with excess ceramide storage in lysosomes. It is characterized by the triad of subcutaneous nodules over extensor joints, painful arthritic joints, and hoarseness due to laryngeal involvement (Figure 104-5). The nodules may involve the eyelids, lips, and gums. Less than 100 cases are reported since the first cases in 1957. Due to the extremely small patient population, the natural history and underlying pathophysiology of this disease are poorly described (311).

**FIGURE 104-5** Farber's disease: subcutaneous nodules over extensor joints.

### 104.8.2 Clinical Description

Up to seven clinical variants are described. An extremely rare and fatal neonatal form presenting with hydrops fetalis is reported. Neonates may present during the first week of life (312). A rare presentation in the neonatal period is cholestatic jaundice and rapidly evolving liver failure (313). The classic variant is the most common with presentation between 4 months and 4 years. All cases manifest the triad. A variable number have lung infiltrates, cherry-red spots, organomegaly, progressive neurological deterioration with the CNS, anterior horn cell, and peripheral nerve involvement. Most die within 1–2 years of onset. Mild and intermediate forms exist with mild or no neurologic involvement. A neurologically progressive form exists with milder visceral disease with little if any organomegaly and no lung infiltration. One unusual case with simultaneous Farber's disease and Sandhoff disease has been described (314). Prosaposin deficiency, with resultant SAP A, B, C, and D deficiencies, causes symptoms characteristic of Farber's disease and Gaucher disease (GD) type II. These patients develop seizures, organomegaly, and respiratory and cardiac failure (315). Patients may present with nodular swellings around the joints, leading to misdiagnosis as juvenile idiopathic arthritis, or the angle of the mouth and conjunctiva. This disease is usually lethal within the first two decades of life (11,316).

Diagnosis of Farber's disease is confirmed by the demonstration of deficient aCDase activity and subsequent storage of ceramide. Existing methods for diagnosis include complex assays with radiolabeled compounds. A new fluorogenic method offers a rapid and accurate determination of aCDase activity and, consequently, the diagnosis of Farber's disease (317). Prenatal diagnosis is achieved by measuring ceramidase activity in CVSs (316). FD is diagnosed by demonstration of reduced aCDase activity and/or abnormally high ceramide levels in cultured cells, biopsy samples or urine, and the presence of "Farber bodies," comma-shaped curvilinear tubular structures, by transmission electron microscopy.

### 104.8.3 Pathology

There are prominent macrophages and histiocytes, as well as foam cells. These sometimes form multinucleated cells around central foam cells. Skin, joints, and larynx have granulomatous regions. The lungs, including alveoli, are infiltrated by many macrophages. Aortic and mitral valves occasionally are thickened with nodules. The brain shows storage material in neuronal cells. Anterior horn cells, brainstem nuclei, cerebellum, basal ganglia, and cortical and retinal ganglion cells can be involved. Ultrastructural studies demonstrate tubular structures in the cytoplasm representing ceramide and zebra bodies consistent with the storage of gangliosides.

### 104.8.4 Biochemistry

In severely affected cases, ceramide content of subcutaneous nodules, liver, kidney, and brain can be quite high. Mildly affected cases may have normal levels. Other glycolipids, particularly gangliosides, accumulate. PM and mitochondrial membrane ceramides have important biomodulatory roles in cell growth, apoptosis, and in regulating other cell-stress responses. The lysosomal ceramide that accumulates in Farber's disease does not cause increased apoptosis of cultured fibroblasts. There are other neutral and alkaline ceramidases active in different compartments of the cell that are distinct from aCDase. ACDase is a heterodimer made up of a longer glycosylated  $\alpha$ -subunit and a nonglycosylated  $\beta$ -subunit. ACDase (*N*-acylsphingosine deacylase, EC 3.5.1.23) is the lipid hydrolase responsible for the degradation of ceramide into sphingosine and free fatty acids within lysosomes. ACDase not only hydrolyzes ceramide into sphingosine, but also synthesizes ceramide from sphingosine and free fatty acids in vitro and in situ. This "reverse" enzymatic activity occurs at a distinct pH from hydrolysis ("forward") reaction (6.0 vs. 4.5, respectively), suggesting that the enzyme may have diverse functions within cells dependent on its subcellular location and pH. ACDase plays a central role in sphingolipid metabolism, controlling levels of ceramide and sphingosine that regulate many vital cellular processes like proliferation, growth, and apoptosis. Animal studies revealed that aCDase knockout (*Asah1*<sup>−/−</sup>) mice had a lethal phenotype (318). Saposins (sphingolipid activator proteins) are soluble glycoproteins necessary for the presentation of hydrophobic lipids like ceramide to lysosomal hydrolases for degradation. SAP C and SAP D present neutral ceramide for degradation in the lysosome into sphingosine and fatty acid by aCDase. The epidermal water permeability barrier or the intercellular lipid barrier of the stratum corneum is made up of ceramide, cholesterol, and free fatty acids, with the ceramide covalently bound to proteins on the surface of the skin (319). Activation of the ceramide pathway leads to sustained activation of ERK-1/2, redistribution of c-Fos and SOX9, and downregulation of type II collagen. This defines a new mechanism for cartilage degeneration seen in Farber's disease (320).

### 104.8.5 Genetics

Farber's disease is rare. Most cases are offspring of consanguineous marriages. The disease is inherited as an autosomal recessive trait, and mutations in the *N*-acylsphingosine amidohydrolase (*ASAH1*) gene, which codes for the aCDase enzyme, cause the disease. There is a notable absence of Jewish cases. Over a dozen point mutations and exon skipping mutations are known. Most affected cases have less than 5% aCDase activity in leukocytes, cultured fibroblasts, and tissues. Carrier diagnosis is possible using enzyme assays and DNA

analysis. Prenatal diagnosis is possible by measuring aCDase activity or performing lipid cell loading studies in cultured amniocytes or CVSs.

A novel mutation in the eighth exon of the *ASAHI* gene located in the  $\alpha$ -subunit of the aCDase protein was described in two Indian siblings. It is a missense mutation causing replacement of valine by leucine at codon p.L182V 182 (321). The c.502G>T substitution is a novel mutation in a Croatian boy leading to the replacement of glycine by tryptophan at position 168 of the aCDase  $\beta$ -subunit (322).

### 104.8.6 Treatment

BMT has been performed and has resulted in regression of the nodules and the organomegaly. Neurologic deterioration, however, was not impacted. If the selection of cases without neurologic involvement were possible, this would be considered a successful form of therapy. This, however, is not always possible as neurologic deterioration can set in as late as 4 years of age. Experimental therapeutic work in cell model systems with viral gene delivery systems is ongoing.

Current treatment focuses on pain management, physical treatment, surgical correction of contractures and treatment with anti-inflammatory drugs. Considerable and progressive joint involvement may result in the inability to walk and in repeated surgical procedures to improve mobility. Patients usually die in the second decade as a result of respiratory insufficiency.

HSCT may correct the abnormal inflammation and be an option in mild and intermediate forms of Farber's disease without CNS involvement. So far, three patients from Germany were transplanted. All showed improvement in mobility, had less pain and considerable gain of function. Despite this limited experience of HSCT in patients with Farber's disease with CNS sparing, the results are encouraging (323).

Gene therapy using oncoretroviral vectors (RV) could restore enzyme activity in Farber patient cells. Novel RV and LV vectors with the coexpression of aCDase and a cell-surface-marking transgene product human CD25 (huCD25) were used to transduce Farber patient fibroblasts and B cells resulting in the overexpression of aCDase and leading to a 90% and 50% reduction in the accumulation of ceramide, respectively. Vectors were also evaluated in human hematopoietic stem/progenitor cells (HSPCs) and by direct in vivo delivery to mouse models. In a xenotransplantation model using NOD/SCID mice, transduced CD34<sup>+</sup> cells repopulated irradiated recipient animals, as measured by CD25 expression. When virus was injected intravenously into mice, soluble CD25 was detected in the plasma and increased aCDase activity was present in the liver 14 weeks postinjection, suggesting that vector and transgene expression can persist long term. The results of these animal studies represent significant progress

toward the development of gene therapy strategies for Farber's disease (324).

## 104.9 ACID LIPASE DEFICIENCY (WOLMAN DISEASE AND CHOLESTERYL ESTER STORAGE DISEASE)

Wolman disease (WD) and cholesteryl ester storage disease (CESD) disease result from defects in acid lipase, which causes the accumulation of cholesteryl esters and TGs in the spleen, liver, BM, intestine, adrenal glands, and lymph nodes. WD manifests after 2 weeks and before 1 year of age with abdominal distension due to a large liver and spleen, steatorrhea, failure to thrive, and adrenal calcification, which is the hallmark of this disease (Figure 104-6). Most patients die by 6 months of age (171).

Although worldwide incidence is estimated at 1/350,000 newborns, WD occurs at higher than expected frequency in the Iranian Jewish community of the Los Angeles area. In the Iranian Jewish population, a heterozygous frequency is 3.086%. Prevalence for couples at risk is estimated to be as high as 1 in 4200 newborns. Additional studies are required to determine if populations of Middle Eastern descent are at a higher risk for WD (325).

CESD has a prevalence of <1/2000. It is more benign and is seldom detected before adulthood. Hyperbetalipoproteinemia and a large liver are the presenting symptoms. Patients may be completely asymptomatic at diagnosis (326). CESD usually presents during the first or second decade of life with males and females equally affected. The phenotype of CESD is highly variable. Abdominal pain is common and is often accompanied by growth failure and chronic diarrhea (105). Hepatomegaly, splenomegaly, and malabsorption are usual. Gall bladder dysfunction (GD) has also been reported (327). Long-term complications include premature atherosclerosis and stroke (55), BM suppression, and testicular storage (21). Patients with CESD may develop progressive liver failure necessitating liver transplantation. Sometimes, CESD is associated with mesenteric lipodystrophy. One case of cholangiocarcinoma has been reported in an adult patient with CESD (166).

FIGURE 104-6 Wolman's disease: adrenal calcification by X-ray.

Hepatocellular carcinoma (HCC) complicating CESD was serendipitously found during liver transplantation in an 11-year-old patient with the disease (328).

Human lysosomal acid lipase/cholesteryl ester hydrolase plays a crucial role in lysosomal hydrolysis of TG and cholesterol esters. Deficient hydrolysis results in lysosomal accumulation of nonhydrolyzed cholesterol esters and TGs and the upregulation of endogenous cholesterol and LDL synthesis. Biochemical evaluation commonly reveals liver dysfunction, increased total cholesterol and LDL cholesterol, decreased HDL cholesterol, and slightly elevated TGs. Pathologic atherosclerosis may potentially be significant, but most patients do not present with cardiovascular disease. Neurologic symptoms are typically absent from both. Diagnosis is made by demonstrating low acid lipase activity in leukocytes or cultured skin fibroblasts. Human lysosomal acid lipase is encoded for by a gene on the long arm of chromosome 10 (gene locus 10q24–25). Currently, more than 50 mutations have been described (262). Both WD and CESD are allelic, autosomal recessive variants. The former is due to the total absence of enzyme activity and results from a number of mutations. CESD patients, on the other hand, usually have 5% or more acid lipase activity. The (934G→A) allele, when present, is predictive of CESD. Compound heterozygosity is the rule (11) in CESD with the majority being carriers of a splice junction mutation (E8SJM). The prevalence has recently been calculated to be as high as 25/106 (20,327). Recently reported mutations include a novel nonsense mutation c.652 C>T (p.R218X) and a complex insertion/deletion leading to a premature termination codon at position 82 (329). No obvious genotype–phenotype correlation has been firmly established (272,326). Carrier diagnosis and prenatal diagnosis by measuring enzyme levels in fibroblasts, amniocytes or chorionic villi, respectively, have been achieved.

Pathologically, lipid-laden foam cells are seen in the digestive tract and aorta, liver, and other organs as well. The BM may show lipid-laden foam cells; for example, sea-blue histiocytes (20,141) and storage macrophages, which can be differentiated from Gaucher or pseudo-Gaucher cells only by an experienced pathologist. Micro- and macro-vesicular steatosis can be seen. Portal and periportal fibrosis may be marked, and there may even be frank cirrhosis. CESD can be distinguished from other lysosomal storage disorders by the examination of frozen liver sections under polarized light. In CESD, liver tissue reveals birefringence that disappears on heating to 50–60°C and reappears on cooling. Heat-sensitive birefringence of liver tissue is highly suggestive for CESD and WD and is not observed in other lysosomal disorders (166). Ultrastructurally, lucent lipid droplets with an electron-dense rim are apparent. In rare cases of WD, sudanophilic material is seen in neurons, glia, endothelial cells, and Schwann cells in peripheral nerves. The adrenals have a yellowish appearance and are difficult

to cut because of a gritty consistency. They are increased in weight due to the deposition of cholesteryl esters and TGs.

Treatment is nonspecific. Suppression of cholesterol synthesis and apolipoprotein B production with HMG-CoA reductase inhibitors is recommended, and has led to improvement in hepatosplenomegaly, HDL levels, and adrenal dysfunction in CESD. Whereas WD is usually lethal, current therapy of CESD consists of a low-fat diet and lipid-lowering drugs such as lovastatin and cholestyramine. The youngest reported patient in the literature treated with HMG-CoA reductase inhibitor is a 2-year-old boy (330). Single reports show increased efficacy by adding ezetimibe to the statin (331). Therapy with intravenous alimentation or dietary supplementation has failed to improve the prognosis of WD. Patients with decompensated liver cirrhosis may require transplantation.

BMT has only had a minor therapeutic impact, owing to the need for matched donors and cachexia of affected individuals (55,332). Krivit et al. (333) reported successful BMT in a 6.5-month-old child with WD (334). Tolar et al. reported long-term survival in four Wolman patients, two of whom are the longest survivors to date (4 and 11 years). Results showed resolution of diarrhea within weeks after engraftment, normalized hepatic function, improved hepatosplenomegaly, and in one patient normal adrenal function. The older patient had normal adaptive functions but mild to moderate neurocognitive deficiencies. The younger patient had age-appropriate neurodevelopment and adaptive abilities (335). Despite this report, WD remains fatal almost universally.

Curing this disease with stem cell transplantation is extremely challenging, with the majority of attempts resulting in death because of liver failure from sinusoidal obstruction syndrome, as well as other transplant-related complications including infection, GVHD, and the failure to engraft (336). Unrelated umbilical cord blood transplantation (UCBT) to treat WD may be more promising (21,332). One paper reported the successful use of umbilical cord blood or UCB-derived stem cells from unrelated HLA-mismatched UCB-derived stem cells in an infant with WD. The patient underwent UCBT at 3 months of age, and her psychomotor development at age 4 years seems to be normal, although laboratory results are suggestive of gonadal failure. The transplantation may result in the restoration of normal acid lipase levels before the onset of permanent end-organ damage and, if performed early, can potentially cure the disease (334).

Plant-produced recombinant protein is active in vitro and in vivo. Intraperitoneally administered active enzyme into deficient mice produced normalization of hepatic color, decreases in hepatic cholesterol and TG contents, and diminished foamy macrophages in liver, spleen, and intestinal villi (332). Transgenic acid lipase-deficient mice injected intravenously with adenoviral vectors containing human acid lipase cDNA (Ad-hLAL)

had increased hepatic enzyme activity, decreased hepatomegaly, and a partial normalization of histopathology, compared with saline-injected controls. Mice showed TG reductions in liver, spleen, and small intestine of 68, 54, and 50%, respectively, and cholesterol reductions of 55, 52, and 34%, respectively, at 20 days postinjection (263,331).

Studies show specific cellular targeting and physiologic effects of differentially oligosaccharide-modified human lysosomal acid lipases and that lysosomal targeting of mannose-terminated glycoproteins occurs and storage can be eliminated effectively (337).

### 104.9.1 27-Hydroxylase Deficiency or Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis (CTX) is a relatively rare disorder described in Jews of north African descent, a group of Japanese cases, and Arab Druze communities, Italy, The Netherlands, and Pakistan. The defect arises because of deficiency in 27-hydroxylase (215,257) which leads to a block in bile synthesis, and accumulation of substrates for this enzyme, including cholesterol, resulting in an increase in the conversion of cholesterol to cholestanol. There is widespread tissue deposition of cholestanol and cholesterol, resulting in tendinous xanthomas, juvenile cataracts, progressive neurological defects, and premature death from arteriosclerosis (338). Plasma cholesterol is often normal, but cholestanol levels are always elevated. Patients can present with cataracts, ataxia, mental retardation or dementia, seizures, a peripheral neuropathy, and xanthomas. Osteoporosis has been described. Spasticity and spastic paraparesis are the most common and relevant clinical hallmarks of motor system involvement in CTX. Cerebellar signs are frequent in CTX phenotype, but contribute less to disability (339). Occasionally, psychiatric disease may precede neurologic involvement. Behavioral and psychiatric manifestations may include attention deficit hyperactivity disorder (ADHD) and oppositional defiant disorder (340). Some manifest before the age of 15 years or in childhood; others do not become symptomatic until later. Parkinsonism and oromandibular dystonia rarely occur (341). Achilles tendon xanthomas are common. These tendon xanthomas can develop later in the third or fourth decade of life. Cardiac manifestations are less frequent and may include coronary obstructive disease (342). Liver involvement is described in patients with neonatal cholestasis (105). Prolonged jaundice occurs more often in adult CTX patients than in the general population (55,343).

### 104.9.2 Diagnosis

CT and MRI are notable for atrophy and focal lesions in the basal ganglia and cerebellum. The diagnosis should be suspected in any one with tendon xanthomas and normal

or elevated cholesterol and in cataracts with a juvenile onset. Diagnosis is usually made by measuring cholestanol levels in plasma. Elevated cholesterol precursors other than cholestanol, including 7-dehydrocholesterol (7DHC), 8-dehydrocholesterol (8DHC), lathosterol, lanosterol, and sitosterol, can be a hallmark for CTX (344). Carriers can be distinguished from normal by an abnormally high excretion of bile alcohols in the urine after a cholestyramine challenge. The assay for the enzyme is available, but tedious (176). Treatment effects can be noted radiologically with brain single-photon emission computed tomography (SPECT). Cortical volume is diffusely decreased in CTX patients and correlates closely with the patient's clinical status. Magnetic resonance-based quantitative metrics allow accurate and objective estimation in lesioned and normal appearing brain (345). Proton MR spectroscopy showed significant signal increases in lactate and decreases in NAA above the lateral ventricles and in the cerebellar hemispheres. Response to treatment can be documented by observing decrease in lactate within cerebellar lesions (109). Transcranial magnetic stimulation (TMS) represents a sensitive indicator of corticospinal tract dysfunction and subclinical improvements in pyramidal function after chenodeoxycholic acid (CDCA) therapy (339).

### 104.9.3 Pathology

Cholestanol is found in tendon xanthomas. Yellow xanthomas are sometimes seen in the cerebellum. There is atrophy of the cerebellar folia with Purkinje and granule cell loss and demyelination. Areas of demyelination are characterized by needle-shaped clefts. These often contain multinucleated giant cells with a foamy cytoplasm. The gray matter is usually not affected. Granulomatous lesions have rarely been documented in the vertebrae, femur, and the lung. In the peripheral nervous system (PNS), there is cholestanol accumulation within Schwann cells, with severe loss of myelinated fibers, predominantly larger diameter myelinated fibers. Axonal degeneration may be secondary to the loss of myelin sheath in CTX. Lipid granules in cytoplasm of Schwann cells with apoptotic nuclei are seen. Fibrous tissue is arranged in parallel on the surface of the tendinous xanthoma (346).

### 104.9.4 Genetics

The gene was discovered in 1991 (276). The CYP27 gene is located on chromosome 2q35-qter. About 50 different mutations are identified in the CYP27A1 gene. DNA diagnosis is possible in a family with a known gene defect. A recent report in Italian patients described four novel mutations located in exons 2–5 of the CYP27A1 gene. The first one is a nonsense mutation in exon 4 (Ser251X). The second mutation, Gly145Arg, is located outside functional domains. The glycine at highly conserved position 145 most likely has a key role in enzyme

function (22). The third mutation (c.647-1 G>T) occurs in the AG consensus acceptor site, a highly conserved site affecting normal splicing, leads to an aberrant protein. The fourth mutation (c.863 delA in exon 5) results in a frameshift from glutamic acid at position 288 (Glu288fs) causing alterations in protein function (347). A novel mutation in exon 1 (11\_12insTGGGCT-GCGC) was described in two Argentinian siblings who developed mental retardation and cataracts without tendon xanthomas (348). Recently described mutations include 1017G>C (exon 5) (349) and a nucleotide deletion (c.1330–1333delTTCC) that results in a frameshift and the occurrence of a premature stop codon leading to a truncated protein of 448 amino acids (350). Another novel (R104Q) mutation was reported in a Japanese patient (351). Other novel mutations include base substitutions in exon 8, C478A, and C479A, which may affect the heme-binding domain of the enzyme (352) and a novel (c.11\_20dup) mutation in a compound heterozygous form. This latter mutation causes an early frameshift and consequent amino acid sequence alterations leading to a premature stop at the 175th amino acid position of CYP27A1 (p.Arg8fsX175) (353).

### 104.9.5 Treatment

It is most important to make the diagnosis of CTX as early as possible. Treatment with CDCA and HMG-CoA reductase inhibitors, if instituted during childhood, will prevent neurologic deterioration and may even lead to improvement (176). If diagnosed neonatally, prompt treatment may prevent the onset of neurological problems (354). In a 14-year study, prompt preclinical administration of CDCA completely prevented the CTX phenotype in two sisters. Prevention is particularly significant in light of the availability of early genetic diagnosis of CTX and the devastating effects of this illness when not treated. Three essential steps can prevent irreversible multiorgan damage in patients with CTX: (1) recognition of early symptoms, especially chronic diarrhea and juvenile cataracts, (2) definitive diagnosis of CTX biochemically and by mutation analysis, and (3) prompt treatment with CDCA to prevent the CTX phenotype (355). Treatment with farnesoid X receptor ligands can promote liver regeneration of patients with low bile acid levels. This could be developed clinically to promote liver regeneration in CTX (169).

Oxidative stress may be a critical component to the neurodegenerative process in CTX. In one study, CML adducts within foamy histiocytes were found in CTX cerebellar tissue, consistent with the presence of reactive oxygen species (ROS). This is supported by the fact that CDCA is important in absorbing fat-soluble vitamins, so untreated patients might be relatively deficient in antioxidant defenses (356). This may provide a rationale for the combined treatment of chenodeoxycholate with antioxidants.

A young man with CTX was on high-dose steroids for a misdiagnosed chronic inflammatory demyelinating polyneuropathy. He had a normal level of serum cholestanol, and when steroids were discontinued, markedly elevated serum cholestanol was measured concomitant with marked clinical worsening. This observation may imply that steroids can lower plasma cholestanol, possibly by directly inducing residual CYP27A1 activity, or alternative pathways for cholestanol elimination (357).

## 104.10 GAUCHER DISEASE

### 104.10.1 Introduction

GD is the most common lysosomal storage disorder. It arises because of the deficiency in the lysosomal hydrolase, acid  $\beta$ -glucosidase (263,358). It results in the accumulation of glucosylceramide, mainly in mononuclear phagocytes, which is responsible for the hepatosplenomegaly seen, as well as many of the other symptoms of the disease (359). Three types of GD are described: non-neuronopathic or GD type I, acute neuronopathic or GD type II, and subacute neuronopathic or GD type III.

### 104.10.2 Clinical Presentation

**104.10.2.1 Gaucher Disease, Type I.** This non-neuronopathic form of GD encompasses the majority of patients with GD in North America and Europe. Although this disease is panethnic, the prevalence is high in Ashkenazi Jews (1 per 850) compared to other populations (1 per 40,000). Age of presentation can be anywhere from infancy to the eighth decade. Initial presentation may be at birth. Most patients present with hepatosplenomegaly, BM abnormalities leading to anemia and thrombocytopenia, and bony changes due to the expansion of the marrow space. Mildly symptomatic patients are diagnosed later in life. Visceral disease is best understood in terms of distribution of storage cells or “Gaucher cells” in the RES. These are macrophages filled with insoluble glycolipids and derived from senescent WBCs and RBCs. Fatigability is a common complaint due to anemia and increased proinflammatory cytokine secretion. Splenomegaly is present in 90% of patients and splenic infarction is one of the more serious complications of this disease. Liver failure, cirrhosis, and portal hypertension occur in less than 10% of cases (360). At the beginning, thrombocytopenia is explained by splenic sequestration of platelets, and responds to splenectomy. In splenectomized patients, it is due to marrow failure as a result of invasion by Gaucher cells. Lymphoproliferative disorders, malignant proliferations, amyloidoses, and gammopathies occur with a greater frequency in GD-I patients than in the overall population. Skeletal involvement is frequent and ranges from osteopenia to severe destructive lesions. Medullary infarction, evidenced by 99m-technetium bone scintigraphy,

is not uncommon. Degenerative joint disease due to aseptic osteonecrotic lesions (particularly of the hips), thinning of cortical bone, and sacroiliac osteosclerosis are frequently described. Pulmonary involvement is rare, but may occur due to the infiltration of alveolar spaces, perivascular, peribronchial, and septal region by Gaucher cells. A restrictive lung syndrome may also occur due to hepatosplenomegaly or kyphoscoliosis (361). Pulmonary hypertension is a complication of GD. The clinical course varies widely. Patients homozygous for the c.1226A→G mutation demonstrate minimal progression during adulthood, whereas clinical manifestations appear to be progressive in the majority of adult and pediatric patients who are compound heterozygotes. Oral findings in the absence of clinical symptoms may lead to early diagnosis of GD. These are yellow pigmentation of the oral mucosa and petechiae, delayed eruption of permanent teeth (56% of young patients <20 years of age). Jaw involvement is often asymptomatic and can be detected as an incidental finding on routine dental radiographs including generalized osteopenia, loss of trabecular structure, effacement of lamina dura, and displacement of the mandibular canal, pseudocystic radiolucent lesions, and apical root resorption of teeth adjacent to the lesions, all of which appear in the mandible (362).

Although type I GD spares the CNS, Parkinson's disease (PD) has been reported as a late feature in GD-I patients. Furthermore, GD heterozygote state is now the strongest genetic risk factor for PD (4–5% of sporadic PD). About 60 patients with GD-I and adult onset PD have been reported. Pathology shows brainstem Lewy bodies and perivascular Gaucher cells characteristic of GD (11,20,21,55,56,105). GD-I may be asymptomatic or cause mild cytopenia and visceromegaly, and may be worth screening in patients from endemic ethnic groups presenting with PD. Clinicians should be aware of this association between atypical Parkinsonism and GD, which may be included in the list of etiologies of corticobasal syndrome (363). Relative to the general population, Parkinsonism in GD patients was more frequent, occurred at an earlier age, responded less well to levodopa, and was more frequently associated with signs of cortical dysfunction. ERT and SRT were ineffective in GD-associated Parkinsonism, suggesting that Parkinsonism itself is not an indication for ERT or SRT in this setting (364). Another rare but fatal complication of Type I GD is pulmonary hypertension that typically occurs in asplenic patients, and may arise via direct involvement of endothelial cells in the disease process (365,366). Other examples of unusual complications include myocardial involvement (367) and peripheral neuropathy (368,369). The principal manifestations of type I GD (increased risk of bleeding, anemia, splenomegaly, hepatomegaly, and bone disease) affect females during reproductive events such as menarche and menstruation; fertility, pregnancy, parity, delivery and lactation; and menopause. Enzyme therapy with alglucerase and/or imiglucerase may reduce

menorrhagia, spontaneous abortions and complications associated with delivery, and the postpartum period. Menarche may be delayed in girls with GD. Menorrhagia is common in GD and is ameliorated by alglucerase/imiglucerase. There is no evidence of decreased fertility in GD. Pregnancy in GD may be complicated by hematological disease, organomegaly, and bone involvement. GD is often diagnosed in pregnancy. There is a reduced risk of spontaneous abortion in women treated with alglucerase/imiglucerase; reduced risk of GD-related complications during delivery, and a reduced risk of GD-related complications during the postpartum period. There are no adverse effects of alglucerase/imiglucerase on the fetus or infants breast fed by mothers receiving alglucerase/imiglucerase. The impact of GD on menopause requires further study in relation to bone pathology (370).

**104.10.2.1.1 Neuronopathic Variants: Types II and III.** These variants manifest CNS involvement with many distinguishing features. Accumulation of glucosylceramide in CNS neurons occurs, but neuronal cell death not storage explains the symptomatology.

**104.10.2.1.2 GD, Type II.** GD, Type II, is the most severe form and is characterized by early onset and rapid disease progression. Formerly known as the acute infantile form, GD II accounts for less than 1 case per 500,000 births. The onset is declared by bilateral fixed strabismus and/or bulbar signs, progressive spasticity, and choreo-athetosis within the first 3–6 months of life, followed by neurological deterioration. Convulsions are observed in some patients. Death ensues during the first 2 years of life, due to psychomotor deterioration. Gaucher cell infiltration of the lung, liver, and spleen is the rule. The neurological presentation of type II GD is homogeneous and characterized by precocious, severe, and rapidly progressive brainstem degeneration. Frequent initial signs are hyperextension of the neck, swallowing impairment, and strabismus. Provoked asphyxial episodes and prolonged spontaneous apneas are main features. Epilepsy, myoclonic epilepsy/myoclonus, trismus, stridor, and progressive microcephaly are less characteristic. Psychomotor regression may occur, but is not a typical feature of the disease onset. Chronic or subacute pulmonary disease predominates in visceral involvement. Hepatosplenomegaly, failure to thrive, thrombocytopenia, and anemia are other remarkable, nonspecific, features. The inflammatory component of GD is underlined by unexplained fever (371).

**104.10.2.1.3 Gaucher disease, Type III.** Gaucher disease, Type III, has a later onset and a more protracted course. It accounts for less than 1 case per 100,000 births. A number of cases have been described from the northern Swedish region of Norrbotten. A functional differentiation between GD types II and III is based on the presence of bulbar signs in type II and their absence early on in type III as well as age of onset (372). Visceral involvement is moderate in GD III, but disease course is severe here with dementia and ataxia. GD III has been

further subdivided into three entities. Type IIIA is the Norbotten form. Type IIIB develops in early childhood with visceral disease manifestations resulting in death due to pulmonary and/or portal hypertension. Type IIIC (mutation c.1342G→C(D409H)) has few visceral manifestations, but has early-onset oculomotor paralysis. Individuals homozygous for this mutation may have mitral and aortic valve involvement, nonatherosclerotic coronary artery disease, hydrocephalus (166,369), and myoclonic epilepsy (55,94,289,366,369,373,374).

There is increased risk for malignancy in patients with GD with a relative risk estimated at 3.6 in one report. The most consistent association of GD and cancers is that with hematological malignancies like lymphoma, myeloma, and leukemia (relative risk 14.7). There is an association between GD and multiple myeloma. The association of GD and multiple myeloma in a population of mixed ethnicity is not fortuitous, although the link between the two has still to be defined. From the clinical point of view, the association remains infrequent and may not drastically change the management of patients with GD. Clinicians must keep in mind the sixfold increase of multiple myeloma incidence in GD patients, and thus pay particular attention to proteinuria, uncommon bone lesions, or clinical evolutions in patients older than 50 years (375). Solid tumors in patients with type I GD are documented in lung, bone, spleen, breast, prostate, colon, brain, and liver (21,22,56,171,175,176,181,272,301,376). All observed carcinomas or tumors develop in systems or organs that harbor GD cells. It is hypothesized that chronic stimulation of the immune system by the accumulation of glucocerebroside may lead to hematological carcinogenesis, whereas damage to the immunosurveillance system of T lymphocyte function may contribute to the development of solid tumors (166,377). Injured macrophages may release secretory products such as ferritin that promote carcinogenesis. There is no solid evidence of a causative relationship between GD and tumorigenesis. The association may just be coincidental (209). Two cases of HCC associated with GD are reported (55,105). Other conditions coexistent with GD may play a role in hepatocarcinogenesis. These are hepatitis B infection and the use of HCG-contaminated analogs of human  $\beta$ -glucocerebrosidase (378).

A strict division in three different forms has been the subject of debate. In a study of a large Dutch cohort of type I GD patients, presence of neurological disease occurred 34 times in 75 patients. Forty-five patients reported at least one neurological symptom during the median follow-up time of 11 years. There are 86 studies in which type I GD patients or carriers of a glucocerebrosidase mutation were described in association with the neurological disease. Non-neuronopathic GD may be an inappropriate characterization of type I GD. The neurological signs and symptoms in type I GD are different and much less severe than the signs and symptoms associated with types II and III disease. Type I disease

should therefore be classified as a separate phenotype. Given the many neurological symptoms and diseases in the Dutch cohort and the many reports on central and peripheral neurological involvement in the literature, the word nonneuronopathic is somewhat problematic. As the neurological changes in type I GD are of a different kind and, of much less severity in comparison with the changes associated with type II and III disease, the presence of neurological changes in type I disease should not lead to the concept of a continuum of symptoms and signs in the three types of GD (379).

At the extreme end of the phenotypic continuum is the perinatal lethal variant, typically presenting in utero or the neonatal period as hydrops and/or congenital ichthyosis, with severe and progressive neurological involvement. Insights from the null-allele Gaucher mouse model significantly contributed to the appreciation of this phenotype by unraveling the critical role of glucocerebrosidase in fetal development. While multiple mutations are encountered, many affected infants are homozygous for recombinant alleles. The diagnosis is often missed due to early lethality and the failure to recognize the association between lysosomal disorders and hydrops fetalis. The incidence of severe perinatal GD may prove more common than previously appreciated. The differential diagnosis of hydrops fetalis and/or congenital ichthyosis should always include lysosomal storage disorders, particularly GD. Diagnosis will enable accurate genetic counseling and facilitate prenatal diagnosis for families affected with this disorder (380).

### 104.10.3 Pathology

This disease is characterized by gliosis in the brain and fibrosis in the visceral organs. In the viscera and bones, infarction, necrosis, and scarring occur. In the brain, the most obvious manifestation is neuronal loss. Unlike other lysosomal storage diseases, most of the storage material in Gaucher cells in viscera is derived from phagocytosis of cells, cell membranes, and cell debris, and are not from cell-specific glycolipid synthesis. Brain neurons are the only cells where endogenous synthesis plays a role in pathogenesis. Little is known about the mechanism leading from lipid accumulation to disease, particularly in the neuronopathic forms of GD. The general hypothesis is that cell death and injury in GSL storage diseases may be mediated by the inhibition of protein kinase C by lysosphingolipids (381). A number of studies have suggested different causes leading to neuronal cell death among which are downregulation of the neuroprotective protein, BCL-2 (382), and defective calcium homeostasis.

### 104.10.4 Biochemistry

The human acid  $\beta$ -glucosidase is a homomeric glycoprotein. Some studies (292) suggest that the normal enzyme may be dimeric in cells, whereas other data (383) are

consistent with the enzyme being a monomer. Several investigators have suggested the existence of groups of mutant enzymes in GD sources, based on different phenomenologic responses to various modifiers of acid  $\beta$ -glucosidase activity (65,166,280) and altered processing/stability. The two classes of mutant enzymes are (1) those with decreased stability, normal interaction with inhibitors, and severely decreased catalytic rate constants; this group of mutant enzymes has been found mostly in non-Jewish type I, II, and III patients and (2) those with essentially normal stability, decreased affinity for active site-directed inhibitors, and moderately decreased catalytic rate constants; this group of mutant enzymes has been mainly found in Jewish patients.

Occasionally, GD is associated with manifestations without an obvious connection to the enzymatic defect and storage of glucosylceramide. This underscores our poor understanding of the biology of glucocerebrosidase gene or GBA1 mutations and the consequences of glucosylceramide accumulation in macrophages and effects on other cell types. Severe Parkinsonian syndrome described in some patients with type I GD has challenged its non-neuronopathic designation (94,384). Parkinsonian syndrome in type I GD is believed to arise from synuclein aggregation within dopaminergic neurons induced by gain-of-function mutations in GBA1 that lead to protein misfolding (i.e. N370S is such a mutation) or the accumulation of lipids (385,386). The increased risk of multiple myeloma and gammopathies in type I GD is attributed to chronic immune stimulation via activated macrophages (276). In type III GD, a distinct phenotype includes cardiac calcification, nonatherosclerotic coronary artery disease, hydrocephalus (166), and myoclonic epilepsy (94). Colloidion skin is the most severe manifestation of type II disease, a phenotype that is recapitulated in germ line GBA1 null mice (372). Taken together, these observations have challenged the macrophage-centric view of GD. Insights into the pathophysiology of GD have revealed important roles of cell types other than phagocytes in the development of GD (359,369).

### 104.10.5 Diagnosis

Measuring acid  $\beta$ -glucosidase activity in leucocytes delivers the diagnosis. Cultured skin fibroblasts also show decreased enzyme activity and may also be used. Enzymatic activity does not differentiate between the three types of GD since there is no correlation between residual enzyme activity and clinical phenotype. Ancillary diagnostic markers consist of increased activities of the following enzymes in GD patients: substrate-resistant acid phosphatase, ACE, and chitotriosidase. Chitotriosidase is produced and secreted by the pathological storage macrophages (Gaucher cells). Plasma chitotriosidase levels are elevated on average 1000-fold in symptomatic patients with GD and reflect the body burden on storage cells. Chitotriosidase is a member of the chitinase

family of enzymes in mammals. Amongst these is acidic mammalian chitinase, implicated in the pathogenesis of asthma. Chitinases are omnipresent throughout nature and are also produced by vertebrates and play important roles in defense against chitin-containing pathogens and in food processing (387). Changes in plasma chitotriosidase reflect changes in clinical symptoms. Monitoring of plasma chitotriosidase levels is commonly used in decision making regarding the initiation and optimization of costly therapeutic interventions (ERT or SRT). A novel substrate has been developed that further facilitates the measurement of chitotriosidase in plasma samples. It has also been shown that the chemokine CCL18 is 30-fold elevated in plasma of GD patients. Therapeutic efficacy can be assessed by monitoring levels of the enzymes mentioned previously, and demonstrating a lowering of CCL18 plasma levels (259), particularly in patients lacking chitotriosidase due to a genetic mutation (388).

In Ashkenazi Jewish cases of GD I, a small number of mutations are involved, and the diagnosis may be made by the analysis of five common alleles. In the overall population, however, the existence of numerous rare alleles restricts DNA diagnosis to the study of certain cases with an established molecular defect or defects in the gene. Prenatal diagnosis is best carried out by the determination of acid  $\beta$ -glucosidase activity in CVSs at week 10 of pregnancy, or in cultured amniotic cells at week 14 of pregnancy if the fetus is at risk for GD types II and/or III.

Population screening is not recommended, according to the NIH Technology Assessment Panel on GD, as the disease does not meet the population screening criteria. The debate regarding prenatal Gaucher screening is complex. Many healthcare centers in Israel offer prenatal panel screening. Controversy exists over the inclusion of GD in the panel screening, especially since GD screening lacks prognostic reliability. Most screening participants do not discriminate between the specific tests in the panel and are unable to discern between severe, life-threatening diseases and those that are less severe and even treatable. By including screening for GD in the panel screening program, there is risk of a “panel effect,” leading to the termination of a pregnancy positive for GD, without sufficient knowledge of the disease. Increasing medical/public awareness of the disease, its prognosis, and treatment options may reduce the rate of underinformed abortions associated with prenatal screening for GD. For the couple with a genetic susceptibility for GD, especially those at high risk for mutations with severe presentations, prenatal screening should be offered. It is important to explain that the genotype–phenotype correlation is imperfect and the prognosis is variable. Screening must include education about GD and its treatment, genetic counseling, and prenatal options so that the couple may make an informed decision regarding the future of their fetus. Healthcare systems should permit flexibility in screening according to individual preference (389).

Once a diagnosis of GD is confirmed, the focus should be on comprehensive evaluation of all disease domains to establish baseline disease characteristics, to determine candidacy for ERT, and to develop personalized therapeutic goals and monitoring strategy. Quality of life measures and a severity score calculation using one of the novel instruments applicable in the clinic are of value in making treatment decisions. Accurate skeletal assessment is important as it is the site of the most disabling, irreversible complications (369).

All Gaucher patients should receive a comprehensive initial radiologic evaluation for bone disease and ongoing radiological monitoring at least once in every 2 years. Plain X-rays are helpful in assessing bone disease, but MRI remains the most sensitive method for monitoring BM infiltration by Gaucher cells (390).

### 104.10.6 Genetics

Almost 300 unique mutations have been reported with a distribution that spans the *GBA* gene. These include 203 missense mutations, 18 nonsense mutations, 36 small insertions or deletions that lead to frameshifts or in-frame alterations, 14 splice-junction mutations, and 13 complex alleles carrying two or more mutations in cis. The mutations 84insG (84G>GC), c.1448T→C (L444P), and c.1226A→G (N370S) account for 8, 20, and 55% of the patient population with GD I, respectively. The (N370S) mutation is present in 6% of the Ashkenazi Jewish population. Investigation of the previously listed three mutations in Ashkenazi Jewish patients allows diagnosis of 93% of the alleles, and 95.5%, if the IVS2+1G→A allele is included. The three mutations account for only 70% of alleles in non-Jewish populations. The (N370S) mutation is described in patients from Portugal, Spain, Germany, and The Netherlands (158,259,289). In contrast, the most prevalent disease genotype worldwide across many ethnicities is L444P, the homozygous state being associated with severe childhood onset and a high risk of CNS involvement (166,175,181,369). Many deleterious alleles, also known as complex alleles (RecNciI and RecTL), occur in GD patients. These genes arise because of a gene-pseudogene crossing over, conversion, duplication, or fusion event. Their presence correlates with disease severity. Identification of novel mutations continues (373,374,391). Two cases of GD are described with no mutations in the  $\beta$ -glucosidase gene, but defects in the gene for sphingolipid activator, saposin C. The clinical phenotype varies from an asymptomatic course to cases of extreme severity in patients with same *GBA1* genotype and in affected sib pairs (160,369). Genotype–phenotype correlations are weak. The best genotype–phenotype correlation includes the presence of an N370S allele, which predicts the absence of primary CNS involvement due to GD. Yet, carrying one or two copies of the N370S allele, although protective for neuronopathic GD, predisposes individuals to early-onset

PD that is refractory to therapy. Study of sporadic Parkinson patients revealed that 14% of the cohort had mutations in the  $\beta$ -glucosidase gene.

Phenotype is influenced only in part by *GBA1* gene mutations and the important role of genetic/epigenetic modifiers has been invoked but awaits delineation (293,369). Despite advances in knowledge regarding the spectrum of *GBA* mutations, the ability to make prognostic predictions from genotypic data is quite limited. While it is possible to enumerate individual mutant alleles encountered in patients with type I, II, and III GD, this approach has limited utility, since it is the combination of mutations on both alleles that is important in defining the phenotype. Most *GBA* mutations are found in patients with more than one type of GD.

The vast majority of mutations identified have not been found in the homozygous form, and the “severity” of a given mutation is hard to predict, especially those found in only a few individuals. It is becoming increasingly difficult to categorize patients into one of the three classic types. Patients who present in infancy or childhood without neurological signs, in some instances, have been reported to be type I in the original description of the causative alleles. However, the development of neurological signs later in life has subsequently resulted in the reclassification of these individuals as type III. There are patients who seem to fall in an intermediate range between the classic type II phenotype and type III. Ultimately, it may be more accurate to envision the associated phenotypes as a continuum, with the major distinction being the presence and degree of neurological involvement. Clinicians have noted that patients with similar phenotypes may have many different genotypes, even in unique subgroups of patients. Conversely, individuals sharing the same genotype can present with and exhibit different disease manifestations, clinical courses, and responses to therapy. Differences are even observed among siblings and twins. Subjects with genotype [c.1226A4G]+[c.1226A4G] (N370S/N370S) can vary from asymptomatic adults to children with significant organomegaly, growth delay, or bone disease. A review of 35 patients with genotype [c.1448T4C]+[c.1448T4C] (L444P/L444P), each confirmed not to have a recombinant allele, demonstrated phenotypes ranging from death in early childhood to autism to being successful college students. One of the few identified genotype–phenotype correlations involves mutation c.1226A4G (N370S), which is encountered solely in patients with type I disease. Since the observed frequency of c.1226A4G homozygotes is considerably less than expected when calculated from the allele frequency in the Ashkenazi Jewish population, the majority of individuals with this genotype are probably asymptomatic or do not reach medical attention. Although the degree and severity of systemic involvement can vary, for the purpose of genetic counseling, this observation can be reassuring to couples seeking to clarify the phenotypic spectrum that may be associated with

an affected pregnancy. The distribution of mutations differs significantly in patients with the neuronopathic forms of GD. Among patients with type II GD, recombinant and rare alleles are especially prevalent. In patients with type III GD, those primarily manifesting with visceral manifestations often carry c.1448T4C (L444P) and/or c.1504C4T (R463C), while c.680A4G (N188S), c.1246G4A (G377S), and c.1297G4T (V394L) are more commonly seen in patients with myoclonic epilepsy, often together with a null or recombinant allele. One atypical phenotype, which includes calcification or fibrosis of the cardiac valves, corneal opacities, hydrocephalus, and dysmorphic features, is associated with mutation c.1342G4C (D409 H). Not all individuals homozygous for this mutation develop this unique phenotype, and when c.1342G4C is in cis with c.882T4G (H255Q), it presents as a type II phenotype. With patients harboring rare alleles or alleles associated with more than one phenotype, caution must be exercised in prediction of disease severity. One approach to making genotypic predictions is to focus on phenotypes encountered in individuals with homozygous genotypes. Approximately 30 different homozygous genotypes have been reported in the literature. There is clearly a dosage effect with some alleles, such as c.354G4C (K79N), c.680A4G (N188S), or c.1246G4A (G377S), where homozygosity for the mutation results in type I disease, while compound heterozygosity with a null allele leads to a type III phenotype. Likewise, individuals homozygous for c.754T4A (F213I) or c.1448T4C (L444P) usually develop chronic neuronopathic GD, but either mutation together with a null allele is more likely to have a type II phenotype. Mutation c.1504C4T (R463C) is particularly confusing, as homozygotes have been described with type I disease, yet when inherited with a null allele, either type I or type III ensues. While different groups have expressed specific mutant alleles *in vitro*, the results have been variable and difficult to compare. The residual amount of enzymatic activity is not associated with the patient phenotype. As seen in other Mendelian disorders, many factors, including complex alleles, alternate substrates, contiguous genes, environmental/infectious exposures, and many potential genetic modifiers, contribute to all the phenotypes in GD (392).

Type I GD is common in the Jewish Ashkenazi population, both other types are not. Phenotypically, GD-II in Ashkenazi Jews is similar to that in other ethnic groups. Homozygosity for certain Ashkenazi alleles might be lethal, leading to a lower frequency of GD2 explaining why it is so rare in the Jewish Ashkenazi population. No case of homozygous L444P has ever been described in Ashkenazi Jews (393). In view of the high carrier rate (1:17) among Ashkenazi Jews (377), it is intriguing that GDII is so rare among Ashkenazi Jewish children. No Ashkenazi Jewish GD-II cases or L444P homozygous patients has ever been reported in the international Gaucher registry. One Jewish non-Ashkenazi type III patient with L444P/L444P genotype is known, the parents being

first cousins from Kurdistan. The common N370S allele, not associated with neuronopathic disease, accounts for about 75% of mutant alleles in Ashkenazi Jews. Also two of the more common Ashkenazi alleles, 84insG and IVS2+1, are thought to be null alleles. Homozygosity would likely result in early lethality and missed diagnoses. The lack of the expected L444P/L444P patients may be another factor responsible for the relative rarity of this condition in Ashkenazi Jews. An awareness that type II GD can occur, albeit rarely, among Ashkenazi families, is of great value while performing genetic counseling in this population (393).

The majority of Chinese GD patients have an early age of onset, severe hematological and skeletal complications, and neurological involvement, resulting in early childhood death. In 29 cases of GD, 13 were diagnosed as type I, 10 as type II, and 6 as type III. A novel mutation, del 205–209ACCTT, was identified in the heterozygous form with mutation R353W (c.1174C>T) by DNA sequence analysis in five type I patients. Other common mutations in that population include L444P and F213I. The majority of the Gaucher mutations identified in Chinese patients were rare or absent in other populations. With the exception of N370S and R353W found only in the type I form, the majority of these mutations are severe resulting in poor prognosis and types II and III GD (394). In a study including 193 unrelated patients from the Spanish GD Registry, 9 novel mutations (4 missense R395C, R463H, W312R, and V398I, 1 nonsense R359X, 4 frameshift c.708delC, c.1214–1215delGC, c.1439–1445del7, and c.42–65del24) were reported. The prevalence of N370S mutation in Spanish GD patients is one of the highest in Europe, and that of L444P one of the lowest worldwide. Considered together, they account for 68.7% of mutated GD alleles in Spain. The latter contrasts with the findings in closed populations, such as Ashkenazi or Norrbottnian, in which the “founder” effect is evident. In these, the number of mutations giving rise to GD is small, facilitating rapid genetic diagnosis. A wide phenotypic difference was observed within each genotypic group and 9% of diagnosed type I patients developed neurological involvement including Parkinsonism, tremor, hypoacusia, and eye movement abnormalities. Findings indicate a significant genotypic heterogeneity explaining the huge phenotypic variation among Spanish GD patients (395).

### 104.10.7 Animal Models

A glucocerebrosidase-deficient mouse has been produced using the techniques of targeted disruption. Homozygotes died within 34 hours of birth and manifested extensive lysosomal storage of glucosylceramide.

### 104.10.8 Treatment

ERT using Cerezyme® is central to GD management (359,372). The aim of ERT is to reverse the symptomatic

clinical manifestations and prevent fibrosis of viscera. Patients generally respond well to ERT, irrespective of disease severity. Patients who are severely affected respond just as well as mild cases. There is reduction of existing hepatomegaly during the first 6 months of treatment. Hemoglobin levels normalize 1 year after treatment in anemic patients (396) and sooner in splenectomized patients. Bone and lung involvement do not respond as well due to poor enzyme delivery. The inability of the enzyme to cross the BBB limits effectiveness in neuronopathic forms of the disease. The main adverse event is the development of neutralizing antibodies that diminish the response to ERT over time and that manifests as worsening after initial improvement. A disadvantage is the cost and the need for intravenous infusions every 2 weeks (365). ERT was introduced as treatment for non-neuronopathic GD more than 15 years ago. Alglucerase, extracted from human placenta, was the first enzyme treatment modality for GD patients to provide specific treatment. Major limitations of this product were its low degree of reproducibility (because of low number of available placentas), risk of blood-borne infections, and short half-life (about 4.7 min in blood and 2 h in visceral organs including liver and spleen) (281,360). The limitations led to the development of a recombinant enzyme; imiglucerase. Imiglucerase (Cerezyme), a recombinant formulation of human glucocerebrosidase, is generated from transduced Chinese hamster ovary cells, and modified by sequential deglycosylation of its carbohydrate side chains to expose alpha-mannosyl residues that mediate the uptake of the intravenously infused enzyme. This enzyme has a longer half life and lack of blood-borne infection risk. It ameliorates systemic manifestations of hepatosplenomegaly, anemia, thrombocytopenia, and skeletal abnormalities in patients with type I and type III (chronic neuronopathic) GD and enhances health-related quality of life. In a randomized controlled trial involving 29 patients with imiglucerase (287), the primary end point was the improvement in bone mineral density of the lumbar spine. ERT significantly improved hemoglobin, platelet counts, and liver volume but did not repair the bone composition in splenectomized adult Gaucher patients. One randomized trial found no significant difference between imiglucerase and alglucerase. A second randomized controlled trial study (397) showed that low frequency administration of ERT in adult Gaucher type I patients maintains stable disease in most patients. The number of randomized controlled trials in ERT is small, but this treatment option has been administered to ~4000 patients worldwide (398). There is a dose-response relationship for imiglucerase therapy (314). For patients in whom immediate disease control is a priority, or those with life-threatening complications such as hepatopulmonary syndrome and pulmonary hypertension, the initial dose of imiglucerase is 120 U/kg body weight over a 4-week period. Patients may transition to lower-maintenance dosing regimens of 30 and 60 U/kg per month after initial disease control. For adult patients

with less severe disease, initial dosing of 60 U/kg body suffices (369). In the younger patients, there is no clear benefit of high-dose ERT (399). The treatment is well tolerated, and infusion-related adverse events such as pruritus and hives, observed primarily in patients who have developed antibodies to the enzyme, are manageable. ERT is the standard of care for patients with GD type I. Imiglucerase is also given to a majority of GD III patients, as a means of alleviating their systemic problems. ERT, however, does not eliminate the neurologic problems in GD III (400).

Velaglucerase- $\alpha$  is a gene-activated human recombinant glucocerebrosidase being developed by Shire Human Genetic Therapies Inc as an ERT for GD I. In vitro, velaglucerase- $\alpha$  was internalized by human macrophages more rapidly than imiglucerase. Clinical trials in patients with GD demonstrate that the safety and efficacy of velaglucerase- $\alpha$  is comparable with historical imiglucerase data, but head-to-head data are unavailable (401). Although effective in improving organ volume, anemia, thrombocytopenia, bone markers, and biomarkers in patients with GD, some patient needs remain unmet because of the limited availability of ERT, inaccessibility of certain disease sites, and emerging disease manifestations. Cases of type 2 diabetes and metabolic syndrome, as well as hematological, lymphoreticular, and immune system malignancies have been observed in patients with GD, but mechanisms underlying the development of these are not fully understood. Animal studies suggest that these complications may be related to the reduction of glucocerebroside levels by the enzyme administered. Glucosylceramide has an immunomodulatory effect through the promotion of dendritic cells, natural killer T cells, and regulatory T cells. The breakdown of glucosylceramide to ceramide can explain part of these findings (402). Splenectomy for treatment of thrombocytopenia is not recommended as pulmonary (361) and bone involvement worsen in splenectomized patients. BMT and its associated morbidity and mortality are not indicated for GD type I.

SRT aims at reducing tissue GSLs by decreasing production of glucosylceramide. One such drug is the *N*-alkylated imino sugar analog, *N*-butyldeoxynojirimycin or Zavesca®. This drug is now approved for use in patients for whom ERT is not suitable (360). This includes rare cases of allergy/hypersensitivity to imiglucerase, or those in whom venous access is not possible. NB-DNJ or miglustat is used in GD to reduce the formation of glucosylceramide by inhibiting glucosylceramide synthase. Various studies address the efficacy of SRT, which leads to improved blood counts, decreased liver and spleen volumes, and increased quality of life (288,403). A recent study gave comparable results to ERT (24). Major drawbacks of SRT are safety issues. Theoretically, the long-term suppression of GSL synthesis may produce detrimental results, but no major adverse events are reported to date. In patients who received previous ERT, the switch to SRT is well

tolerated (282). SRT is currently limited only to adult GD I patients who cannot tolerate ERT (398). A systematic review of studies examining the effects of ERT and SRT on bony complications of GD I concludes that ERT is very effective in ameliorating BM involvement. The effects of SRT on improving BM disease Z-scores of lumbar spine and femoral neck look very promising and seem to take a shorter period of time compared to ERT (404). Miglustat reduces the incidence of patients reporting bone pain and improves bone mineral density seen within the first 24 months of therapy (405). Two advantages are that it is an oral drug and that it crosses the BBB. Abdominal pain, weight loss, and diarrhea are problematic for patients, particularly during the initiation of treatment. Tremor and a reversible peripheral neuropathy are of concern as well. All patients receiving this treatment should undergo baseline and repeat neurological evaluations at ~6-month intervals. Males may experience infertility due to abnormal spermatogenesis. Downstream effects on vital GSLs beyond glucosylceramide may have deleterious effects on the peripheral and central nervous systems and therefore SRT should not be used in children under 18 or adults over 65, in accordance with FDA-approved guidelines. Because responses to miglustat are slower and less robust than those observed with ERT, and because miglustat is associated with significant side effects, clinicians who care for patients with GD should become familiar with the limited indications for its use and the circumstances when it may be prescribed appropriately.

The available ERT and SRT options are expensive as the annual cost of ERT is around 1 billion US dollars (289), and individual responses for these treatments are highly variable so that some patients may report no improvement. Decision for treatment must be individualized. Severe organomegaly, high degree of cytopenia, minor bleeding due to thrombocytopenia, bone disease, liver enzyme elevations with severe organomegaly, and the presence of any organ involvement other than the liver–spleen–bone triad are indications for treatment. The aims of treatment are reversal of organomegaly, prevention of complications, and improvement in the quality of life. Some patients may not require disease-specific treatment because they have very mild manifestations. Such patients are usually of the N370S homozygous genotype. These patients should be monitored regularly to detect signs of disease progression so that treatment can be initiated before new symptoms/irreversible damage occurs. Maximal therapeutic gains can be achieved by preemptive therapy.

Pharmacological chaperones that can enhance trafficking of certain mutant forms of  $\beta$ -glucosidase (N370S) through the secretory pathway, that are otherwise retained in the ER and degraded, can enhance enzyme activity. These agents penetrate the PM and the ER, and by binding to the folded mutant enzyme population in the ER, shift the equilibrium toward folding allowing mutant enzyme to be trafficked to the Golgi and on

to the lysosome more efficiently, where the high substrate concentration and low pH environment stabilize the  $\beta$ -glucosidase fold enabling it to degrade glucosylceramide. The resulting increase in mutant lysosomal enzyme concentration and cellular activity is beneficial. Eliglustat tartrate (Genz-112638), currently under development by Genzyme Corp, is a glucosylceramide synthase inhibitor for the treatment of GD. In vitro studies demonstrate that, following exposure to eliglustat tartrate, the abundance of GM1- and GM3-gangliosides in cultured human erythroleukemia cells and murine melanoma cells were decreased. In vivo, eliglustat tartrate administered to Asp409Val/null mice lowered the concentrations of glucocerebroside in the liver, lung, and spleen and reduced the number of Gaucher cells in the liver. In a phase Ib clinical trial in healthy volunteers, plasma glucocerebroside concentrations were decreased after dosing with eliglustat tartrate, and in phase II clinical trials in patients with type I GD, spleen and liver volumes were diminished. Patients also reported improved bone mineral density, correction of abnormal BM signal by MRI, and the normalization of glucocerebroside and ganglioside GM3 levels (406). These agents have the potential to be useful for treating patients with type II and III GD, for which there are currently no therapeutic options (407). Use of the  $\beta$ -glucosidase inhibitor, *N*-nonyl-deoxynojirimycin, at suboptimal concentrations in cultured cells has resulted in an increase in enzyme activity. Perhaps a combination of therapies can be tailored for patients. Control of secondary inflammatory changes may also alter disease progression. Further work on pharmacologic chaperones and the development of more efficient ERT or small molecule therapies may lead to improved treatment options (46). Stem cell transplantation is a high-risk procedure with possible long-term benefits in the regression of skeletal and neurological changes in people with GD. There are no clinical trials that have assessed the safety and efficacy of stem-cell transplantation in comparison to other conservative measures (408).

### 104.11 GALACTOSYLCERAMIDE LIPIDOSIS, GLOBOID CELL LEUKODYSTROPHY, OR KRABBE DISEASE

#### 104.11.1 Introduction and Historical Aspects

Krabbe disease (KD) arises because of defects in the galactosylceramidase (galactocerebroside  $\beta$ -galactosidase or GALC) protein that normally degrades the GSL, galactosylceramide. Krabbe's report of two infants who died of a familial and acute form of diffuse brain sclerosis was published in 1916. There were, however, two previous reports consistent with KD by Bullard et al. and Beneke that appeared in 1906 and 1908, respectively (248). Collier and Greenfield introduced the term globoid cells to describe the multinucleated, hematogenously derived

macrophages that are chock full of galactosylceramide (280). These are found in the central and peripheral nervous systems of patients. The symptomatology is entirely neurologic. The most common variant is the infantile form, which presents between 3 and 6 months of age with irritability, extreme spasticity, opisthotonic posturing, and an inability to be consoled by holding. Patients become blind and are severely impaired by the time they die during the second year of life. Late infantile, juvenile, and adult forms exist and are characterized by varying degrees of spasticity, peripheral neuropathy, dementia, and blindness.

### 104.11.2 Clinical Presentation

The most common initial symptoms between ages 0 and 12 months are crying and irritability, stiffness, and seizures. Older children are more likely to present with gait disturbances or loss of milestones. Survival differs depending on the age of onset. Children with the early infantile type (onset 0–6 months) have significantly worse survivals than those with a later onset (409).

**104.11.2.1 Infantile Form.** After a period of normal development, these infants manifest marked irritability, inconsolable crying, and opisthotonous posturing, with hands held in a claw-like position. Touching, stroking, or holding these infants does not have a soothing effect as one expects, but may provoke more crying, perhaps because of hyperesthesias. Psychomotor decline ensues. Although the head may be large, microcephaly is more common. Optic atrophy appears a few months into the illness. One single case has been reported with cherry-red spots. Peripheral neuropathy is often, but not always present. Reflexes may initially be hyperactive, only to disappear later. Seizures are quite common, particularly late in the course. These children seldom live past their second birthday. More recently, a Palestinian Muslim female presented with progressive neurologic deterioration at 3 months of age with rapid decline and death at 8 months of age. She had a defect in sphingolipid activator protein A or saposin A (SAP A).

**104.11.2.2 Late Infantile Form.** The age of onset is from 6 months to 3 years. Manifestations include psychomotor decline, irritability, ataxia, spasticity, loss of vision, and may include peripheral neuropathy and seizures. Children usually die 2 years after the initial diagnosis.

Acquired obstructive hydrocephalus is reported in patients with late infantile and with early infantile forms. CSF protein elevation may cause obstructive hydrocephalus through an effect on CSF drainage. Elevation of CSF protein increases viscosity, slows its circulation, and reabsorption. Elevated CSF protein may produce an aseptic arachnoiditis at the basal cisterns, with irreversible blockage. Functional obstruction at the aqueduct of Sylvius may also occur (410). Seizures may

develop months to years after onset. Rarely do they signal the onset. Myoclonic seizures are an infrequent early symptom (411).

**104.11.2.3 Juvenile Form.** This variant becomes apparent between the ages of 3 and 8 years. Spasticity, ataxia, hemiparesis, and peripheral neuropathy are less common. Ultimately, cognitive and motor declines ensue. In spite of an initial rapid decline, the course levels off over a number of years with some patients surviving into the second decade (412,413).

**104.11.2.4 Adult Form.** These cases are the most difficult to diagnose. Individuals may be neurologically intact during childhood, or they may have some fixed neurologic deficit such as club feet, ataxia, tremor, or rigidity only to deteriorate later in life. In some cases, a late-onset cognitive decline or dementia can set in late in the course. Peripheral neuropathy has been described in some cases, but does not need to be present. A common clinical presentation for the adult form is one of familial spastic paraparesis (377,414,415).

**104.11.2.5 Laboratory Findings.** *Routine Blood Work:* Laboratory values are normal with two exceptions. CSF protein is almost always elevated in infantile and late infantile forms. There have been reports of elevated lactate levels in KD that may falsely point to a mitochondrial problem. Another leukodystrophy in which lactate may be elevated is Alexander's disease.

*Neuroimaging:* MRI and CT can greatly assist in narrowing down the diagnosis to a demyelinating disorder (Figure 104-7). High-signal, T2-weighted changes in the thalami, corona radiata, cerebellum, internal capsule, and periventricular white matter have been described in MRIs from these patients. Rarely, the enhancement of cranial nerves or lumbosacral nerve roots is observed early in the course of infantile cases. The detection of optic nerve enlargement and enhancement on MRI scans, not found in other types of leukodystrophies, is an auxiliary tool in the differential diagnosis of infantile KD (84,416–418). Rarer imaging characteristics of

**FIGURE 104-7** Krabbe disease: demyelinating lesions by CT scan.

early infantile KD include cystic lesions adjacent to the ventricles (419). Enhancement can be seen in the late form between the abnormal white matter and the spared subcortical U-fibers of white matter. Symmetric abnormalities were observed in the pyramidal tracts and optic radiations of an adult patient by fluid-attenuated inversion recovery (FLAIR) MRI. Cases of KD disease with selective involvement of corticospinal tract have been reported only in adults. Case reports of children with predominant involvement of corticospinal tracts are very few, but may show involvement of corticospinal tracts on MRI as the initial feature without other characteristic features of KD (420). Thinning of the spinal cord has also been reported in adult KD (421). Proton MRS has shown increased peaks of choline and myo-inositol with a decrease in *N*-acetyl aspartic acid; the first two findings are characteristic of demyelination, and the last suggests neuroaxonal destruction. The MRS abnormalities are milder with increasing age of onset. Also, lactate peaks by MRS have been reported. Diffusion-weighted MR imaging reveals high apparent diffusion coefficients (ADC) and low apparent anisotropy values before demyelination becomes apparent by routine MRI. These findings distinguish KD from other leukodystrophies such as MLD, Canavan's disease, and Pelizaeus–Merzbacher disease. Radial stripes by MRI have been studied pathologically in KD and correspond to perivenular clusters of globoid cells filled with galactosylceramide. DTI with quantitative tractography may detect significant differences in the corticospinal tracts of asymptomatic neonates who have the early-onset form of KD. DTI has the potential for use as a marker of disease progression in neonates diagnosed through screening programs in addition to monitoring response as future therapeutic modalities emerge (422). Infantile KD is reported to have MRI findings of diffuse cranial nerve/cauda equina nerve roots enhancement. Such findings may exist with or precede typical white matter abnormalities and may facilitate earlier diagnosis. These findings provide a rationale for use of contrast agents and craniospinal MR imaging in a child with a history of psychomotor regression and evidence of peripheral nerve involvement (423).

**Neurophysiological Tests:** Although EEGs may be normal initially, almost all infantile and late infantile cases have notable abnormalities later in the course. Multifocal epileptiform discharges, a slow and disorganized background, as well as asymmetry have been described. Nerve conduction velocities are almost always slowed, especially in the early forms, and often enough in the juvenile and adult forms. Peripheral neuropathy occurs very early in KD and affects the nerves uniformly. Marked nerve conduction abnormalities were found in 1-day-old and 3-week-old neonates, the youngest patients reported to date. The severity of the demyelination on nerve conduction correlates well with the clinical severity of the disease (424). EMG can also be abnormal. Evoked potentials have been closely studied in

the early Krabbe form. BAERs are abnormal in 88% of cases, and flash VERs in 53% of early cases. For the later onset cases, BAERs were abnormal in 40% and VERs were normal in all cases. The severity of the abnormality correlated with more extensive disease by MRI. In the early-onset group, all symptomatic cases had abnormal BAERs, and in the asymptomatic early group 50% had brainstem auditory evoked potential (BAEP) abnormalities. For VERs, 67% of symptomatic cases had abnormalities, but none of the presymptomatic children did (175,425,426).

Diagnosis is confirmed by measuring galactocerebrosidase (GALC) activity in leukocytes or fibroblasts, and occasionally using DNA molecular diagnostics in specific families or ethnic groups (see “Biochemistry” and “Genetics” sections). A novel assay measures  $\beta$ -GALC activity following complete inhibition of  $\beta$ -galactosidase activity. This method unequivocally discriminates cells from healthy subjects and Krabbe patients and is therefore suitable for diagnostic applications. The procedure is straightforward, rapid, and reproducible, and the assay method is ideal for the diagnosis of KD (427). Prenatal diagnosis has been successfully performed on AF cells and CVSs from pregnancies at risk. Carrier detection is possible, though there is an overlap of enzyme values between noncarriers and carriers. It may be helpful to simultaneously assay parents together with those members of the family seeking clarification of their carrier status. When clinical course and neuroimaging studies are supportive of a diagnosis of KD in the setting of normal to minimally low enzyme activity and normal gene sequence for GALC, a defect in the activator saposin A must be suspected. The diagnosis can be made using natural substrate metabolism studies in cultured fibroblasts or DNA analysis of the *SAP A* gene. It is highly recommended that the biochemical assays only be performed in laboratories with experience in the diagnosis of the sphingolipidoses.

**104.11.2.6 Pathology. Central Nervous System:** Pathologic changes are largely limited to the nervous system. The brain is shrunken with large sulci and large ventricles. There is devastation of white matter with relative preservation of gray matter (Figure 104-8). Histologically, there are three striking features: loss of myelin and loss of oligodendroglia, the presence of multinucleated globoid cells, and astrocytic gliosis. Demyelination is most severe in the phylogenetically more recently myelinated structures such as the centrum semiovale and the cerebellum. There is secondary axonal degeneration. Mononucleated and multinucleated giant globoid cells are phagocytic in origin and tend to cluster around blood vessels (Figure 104-9). They are periodic acid Schiff (PAS) positive and stain intensely with acid phosphatase. Experimentally, globoid cells have been produced in murine brain by injection of solid galactosylceramide. Golgi preparations of pyramidal neurons reveal intact dendritic processes. At the end, relatively

**FIGURE 104-8** Krabbe disease: shrunken brain with large sulci and ventricles and relative preservation of white matter.

**FIGURE 104-9** Krabbe disease: giant globoid cells in the brain cluster around blood vessels (arrows).

little myelin is present and there is intense astrocytic gliosis (428–430).

**Peripheral Nervous System:** Peripheral nerves are thickened and rubbery in texture. There is segmental demyelination with variable distances between nodes of Ranvier. There is endoneural fibrosis, fibroblast proliferation, and perivascular presence of PAS-positive macrophages. Axonal degeneration is often present. Schwann cells often contain the typical needle-like tubular inclusions that are also seen in globoid cells in the brain by electron microscopy (426,431,432).

### 104.11.3 Late-Onset Krabbe Disease

Degeneration of the optic radiation and of the frontoparietal white matter with secondary degeneration of the corticospinal tracts has been described in two siblings. Peripheral nerves can be affected and Schwann cells with the typical needle-like inclusions have also been seen in sural nerve biopsies from older patients.

In fetal KD, the spinal cord begins to show abnormalities at about 20 weeks gestation: globoid cells are often observed in the dorsal columns and contain the typical tubular inclusions characteristic for this disease. The pons may be involved. There is no delay in myelination.

### 104.11.4 Biochemistry and Pathobiology

Galactosylceramide and its sulfated form, sulfatide, are major constituents of healthy myelin. The dilemma in KD is that although the hydrolytic GALC enzyme is missing, galactosylceramide does not accumulate in the brains of Krabbe patients or animal models. Multiple explanations have been put forth for this peculiarity. There is substrate specificity overlap between GALC and  $\beta$ -galactosidase, the enzyme deficient in GM1-gangliosidosis. The latter enzyme also can degrade galactosylceramide. Another substrate for GALC, psychosine, which is made up of galactose and sphingosine, or galactosylceramide minus the fatty acid, is not a substrate for  $\beta$ -galactosidase, and accumulates up to 100-fold in preserved myelin. The Krabbe–Psychosine hypothesis correctly claims that psychosine, a potent killer of oligodendrocytes by apoptosis, accumulates. Ultimately, dwindling numbers of oligodendrocytes prevent normal formation and turnover of myelin, which explains the lack of increase in galactosylceramide. Globoid cells, however, are induced by galactosylceramide as has been shown by injecting rat brains with galactosylceramide. Moreover, the needle-like and tubular inclusions seen in Schwann cells and globoid cells are quite similar to galactosylceramide aggregates. GALC was discovered in 1970. Determination of enzyme activity remains the best and quickest test for diagnosis. As stressed previously, the enzyme assay for GALC and the interpretation of results may not be entirely straightforward, and are best carried out in specialized laboratories.

The lysosomal GALC enzyme is involved in the maintenance of a functional HSPC niche by contributing to the control of the intracellular content of key sphingolipids. Both insufficient and supraphysiologic GALC activities,

by inherited genetic deficiency or forced gene expression in patient cells and in the disease model, induce alterations of the intracellular content of the bioactive GALC downstream products, ceramide and sphingosine, and thus affect HSPC survival and function, as well as the functionality of this stem cell niche. GALC and other enzymes may control the concentration of these sphingolipids within HSPCs (433).

Psychosine accumulation in LRs has functional consequences that range from interference with cell signaling to deregulation of raft-mediated endocytosis. Clearance of psychosine from LRs and the recovery of endocytosis are achievable with GALC replacement in vitro (434). The mutation of GALC and the resultant LR-targeted accumulation of psychosine disrupt the normal architecture of rafts. This drives a cascade of events in which there is an interference of protein–protein interactions that normally occurs in rafts, resulting in aberrant cell signaling, which then could lead to a decrease in normal overall cellular function and survival. This series of events should be considered, at the least, as a potential contributing factor in the overall decline in health of those suffering from KD (435). Psychosine accumulation induces an inflammatory process in nervous tissue and likely leads to impaired peroxisomal structure and function. This leads to downregulation of peroxisomes and the loss of peroxisomes, in turn, upregulating inflammatory disease (436). A psychosine-induced inflammatory process also occurs in liver and possibly other organs. The expression of cytokines and their effects on peroxisomal structure/function in Twitcher mouse liver indicate that Twitcher mouse pathobiology extends to the liver, where the induction of TNF- $\alpha$  and IL-6 compromise peroxisomal structure and function (437).

In rhesus macaques, globoid cells and parenchymal microglia express HLA-DR, indicating immune activation. Increased expression of iNOS, TNF- $\alpha$ , and IL-1 $\beta$  were observed in affected white matter, colocalizing with globoid cells, activated microglia, and astrocytes. This data suggest that the dysregulation of monocyte/macrophage/microglia and the upregulation of certain cytokines may contribute to the pathogenesis of KD (438).

The role of inflammatory cells and mediators in KD pathogenesis is suggested by increased production of TNF- $\alpha$  in peripheral blood mononuclear cells and the potentiating effect of psychosine in stimulated cells. Inflammation may be secondary to the damage induced by psychosine accumulation but it partly has a primary role in determining pathogenesis (439). Monocytes from Krabbe patients have a proinflammatory pattern that is amplified by psychosine. Atypical cytokine production suggests the involvement of inflammation in immune peripheral cells (440). Prostaglandin (PG) D<sub>2</sub> is a mediator of inflammation. Hematopoietic PGD synthase (HPGDS) is responsible for the production of PGD<sub>2</sub> involved in inflammatory responses. Microglial activation and astrogliosis occur during neuroinflammation,

particularly demyelination. In the Twitcher mouse, a model for human KD, activated microglia express HPGDS and activated astrocytes express the DP1 receptor for PGD<sub>2</sub> in the brain of these mice. Cultured microglia actively produced PGD<sub>2</sub> by the action of HPGDS. Cultured astrocytes expressed two types of receptors, DP1 and DP2, and enhanced GFAP production after stimulation of receptors with their respective agonist. The blockade of the HPGDS/PGD<sub>2</sub>/DP signaling pathway using HPGDS- or DP1-null *twitcher* mice, and *twitcher* mice treated with an HPGDS inhibitor, HQL-79 (4-benzhydryloxy-1-[3-(1H-tetrazol-5-yl)-propyl]piperidine), resulted in the suppression of astrogliosis and demyelination, and a reduction in twitching and spasticity. Furthermore, the degree of oligodendroglial apoptosis was reduced in HPGDS-null and HQL-79-treated *twitcher* mice. This suggests that PGD<sub>2</sub> is the key neuroinflammatory molecule mediating the pathological response to demyelination in *twitcher* mice (441).

In the *Twitcher* mouse model, neurological symptoms parallel severe lymphopenia. Although lymphopoiesis is normal before disease onset, primary and secondary lymphoid organs progressively degenerate. Hematopoietic cell replacement experiments support the existence of an epigenetic factor in mutant mice reconcilable with a progressive loss of autonomic axons that hamper thymic functionality and loss of immune competence. This finding suggests that KD patients are at risk of immune-related pathologies, and identifies a novel target for therapeutic interventions (442). Saposin A deficient mice demonstrate clinical, biochemical, and pathological phenotypes of a chronic form of globoid cell leukodystrophy (GLD) establishing that saposin A is essential for in vivo degradation of galactosylceramide. Saposin D deficient mice accumulate ceramides containing  $\alpha$ -hydroxy fatty acids (HFA/d18:1) in the brain and kidney and suffer from renal tubular degeneration and cerebellar Purkinje cell loss (443).

Psychosine induces the generation of lysophosphatidylcholine (LPC) and the release of arachidonic acid (AA) via the activation of sPLA<sub>2</sub> activity. Activation of PLA<sub>2</sub> generates ROS. Psychosine-mediated effects are nullified by the sPLA<sub>2</sub> inhibitor 7,7-dimethyleicosadienoic acid, which blocks the activation of mitogen-activated protein kinase (MAPK) and the generation of ROS by psychosine in oligodendrocytes. N-acetylcysteine (NAC) also attenuates LPC accumulation, AA release, ROS generation, and cell death induced by psychosine (4), suggesting involvement of oxidative stress in psychosine-mediated effects in oligodendrocytes. Generation of LPC has been implicated in demyelination (256,257) by the activation of cell death in mature oligodendrocytes and their progenitors (258,259). Metabolites of AA cause oxidative stress, regulating redox sensitive transcription factors (75,141,263) and cell death (261,262). Psychosine-mediated oligodendrocyte cell death is mediated via the sPLA<sub>2</sub> signaling pathway. Inhibitors of sPLA<sub>2</sub> may have

therapeutic potential protecting against oligodendrocyte cell death and demyelination in KD (444).

There is progressive loss of peroxisomal proteins/functions and induction of inflammatory TNF- $\alpha$  in Twitcher brain. The decrease in peroxisomal proteins was accompanied by lowered peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ), a transcription factor required for expression of peroxisomal genes. Psychosine-induced downregulation of PPAR activity and cell death were attenuated by sPLA2 inhibitors. This suggests that the dysfunction of peroxisomes may play a role in the pathogenesis of KD and other lysosomal disorders. Peroxisomes and their function are compromised by psychosine accumulation. This compromised function may be responsible for oligodendrocyte loss and demyelination observed in Twitcher and Krabbe brains. This represents lipid-mediated downregulation of peroxisomal transcriptional activity and peroxisomal dysfunction in a storage disorder with psychosine-mediated pathobiology. Restoration of PPAR- $\alpha$  activity and the inhibition of cell death by sPLA2 inhibitors may provide novel therapies for KD (445). Psychosine accumulates in bones of mice. It may act as a factor or in conjunction with decreased plasma IGF-1 levels, impairing osteoclastic function, stunting bone growth. Treatment regimens may consider supplementation with paracrine factors (446).

### 104.11.5 Genetics

The human gene for GALC was identified in 1993. It consists of 17 exons and 16 introns. It codes for a 669 amino acid protein. The precursor protein is ~80 kDa and is processed to a 50–52 kDa and 30 kDa subunit. Both are important for enzyme activity. About 80 mutations have been reported as a cause of KD [<http://www.hgmd.org>]. A common mutation is the 502T/del, which accounts for 75% of Swedish cases and more than 50% of all European cases, suggesting a Swedish founder effect. There are two other mutations with high-carrier frequency. One occurs in Palestinian Druze (T1748G), and the other in a Palestinian Muslim group from a village close to Jerusalem (G1582A) (297,447–449). The mutation consists of a 30-kb deletion starting with a 502 C-to-T polymorphism beginning in the middle of intron 10 and extending to the end of the gene. This deletion eliminates the entire 30-kDa protein and 15% of the 50–52-kDa protein. All patients homozygous for this deletion have the infantile form of the disease. Recently, a prevalent GALC missense substitution p.G553R (G537R) was described in the Italian population with a high frequency and appears to be due to a common founder haplotype background in patients originating from Naples (450). The founder mutation c.169G>A (121G>A) is responsible for the other known KD “hotspot” in Catania (Sicily), associated with the late-onset form of the disease (451). There are a number of common polymorphisms (C502T, G694A, A865 G, and T1637C) that can occur together, or with disease-causing

mutations on the same allele. Presence of these polymorphisms is thought to contribute to the severity of the phenotypic disease expression. In a recent study of 30 European unrelated patients affected by KD, 15 previously unreported mutant alleles were described. These included four novel missense mutations that replaced evolutionarily highly conserved residues (p.P318R, p.G323R, p.I384T, p.Y490N), most of the newly described lesions altered mRNA processing, seven frameshift mutations (c.61delG, c.408delA, c.521delA, c.1171\_1175delCATTTCinsA, c.1405\_1407delCTCinsT, c.302\_308dupAAATAGG, c.1819\_1826dupGTTACAGG), and three nonsense mutations (p.R69X, p.K88X, p.R127X) one of which (p.K88X) led to skipping of exon 2, and a splicing mutation (c.1489+1G>A) that induced the partial skipping of exon 13. In addition, six previously unreported GALC polymorphisms were identified (450). A recent study in 17 Japanese patients with KD six mutations were novel, including two nonsense mutations, W115X and R204X, two missense mutations, S257F and L364R, a small deletion, 393delT, and a small insertion, 1719-1720insT. The two most frequent mutations 12Del3Ins and I66M+I289V account for 37% of all mutant alleles. With two additional mutations, G270D and T652P, these account for up to 57% of genetic mutations in Japanese patients (452). It is difficult to discern a trend in terms of a genotype–phenotype relationship. In addition to the mutational heterogeneity, the highly variable polymorphic background plays a role in modulating the genotype–phenotype relationship. Clinical phenotypes differ between individuals with the later onset forms of the disease, including siblings. The GALC mutational profile differs between European and Japanese KD patients. The most common large deletion, c.1161+6532\_polyA+9kdel (IVS10del30kb) plus three other mutations [c.1586C>T, c.1700C>T, c.1472delA (1538C>T, 1652A>C, 1424delA)] account for 60% of alleles in European ancestry KD with the classic infantile form (413,453). In the Japanese, these lesions are absent. By contrast, ~30% of Japanese GALC alleles associated with the infantile form of the disease possess c.683\_694del12insCTC or c.2002A>C (635\_646del12insCTC and 1954A>C) (452).

The common 30 kb deletion (c.1161+6532\_polyA+9kdel) is frequently found in patients with the infantile form of the disease (but sometimes with the juvenile form, depending on combination with other mutant alleles). The p.G286D (G270D) mutation might be associated with the juvenile/mild forms of KD. In vitro expression studies indicate that GALC enzymatic activity is absent in association with p.G553R (G537R), and is consequently associated with severe infantile KD in homozygosity or compound heterozygosity. The mutation p.R79H (R63H) is reported in association with the late-onset form of the disease. The p.E130K (E114K) mutation predicts a severe infantile form phenotype (450). The p.Gly41Ser mutation is described in the late-onset form and is associated with longer survival

(454). A high proportion of patients with late-onset forms of KD are observed in a region north of Catania in Sicily in which the founder mutation c.169G>A (121G>A) is described (451). In the Japanese population, I66M+I289M, G270D, and L618S contribute to a mild phenotype (452). Of particular interest is a patient with white matter disease restricted to one hemisphere and no symptoms. The mutation on one allele and the three polymorphisms associated with reduced expression on the other allele were present with enzymatic activity similar to that in heterozygotes without symptoms, or with mild phenotypes. A second somatic mutation in the *GALC* gene or another unidentified modifier gene may be present (455).

### 104.11.6 Animal Models

There are numerous naturally occurring animal models for KD (448,456). The most famous and useful has been the Twitcher mouse. A variety of naturally occurring canine models also exist (West Highland White terriers and others). Much of the work done in the murine model for the disease has provided novel insights into disease severity and progression and has resulted in ideas to approach therapy. There is a fair contribution of inflammatory processes to disease severity in this leukodystrophy. Crossing immunocompromised mice with the Twitcher model has resulted in progeny with attenuated disease severity. Also, apparently estrogens abundant during the pregnancy of some of the mice resulted in milder forms of the illness. Crossing the *GALC*-deficient mouse with a mouse heterozygous for galactosylceramide synthase or transferase gene (*GTC*) resulted in litter with milder disease, suggesting that there is some rationale to substrate reduction as well. The pioneering work on the beneficial effects of BMT KD was also first performed in the Twitcher mouse.

### 104.11.7 Treatment

Beneficial effects of BMT or cord blood transplants have been documented when the procedure was carried out in presymptomatic infants who had older siblings with the disease or in later onset cases (282). In utero BMT has not been successful in the few cases attempted. There are numerous words of caution that must be stated (181,249,333,457–459). Apparently, L-cycloserine is a potent inhibitor of psychosine production and its use as part of the treatment protocol in hematogenously derived stem cell transplantation may be responsible for many of the beneficial effects observed, suggesting its own potential as therapy. BMT or cord blood transplants may not be as helpful in already symptomatic infants and children, presumably because of advanced destruction of oligodendrocytes and the inability of these individuals to ever remyelinate normally. It becomes difficult to deny this extreme form of therapy in some but not all patients.

Although as physicians, we may understand the rationale and ponder the extravagance of expensive and futile drastic treatments, parents are more difficult to convince of their usefulness in some but not all affected children. Numerous other avenues for therapy are being explored in animal models: retroviral and adenoviral transduction of a variety of cells, direct introduction of *GALC* in viruses or liposomes into the brain, direct introduction of controversial stem cells directly in the brain, anti-inflammatory and antiapoptotic oral drugs, and the development of substrate reduction approaches, or combinations of any of the aforementioned approaches. Studies in Twitcher mice using gene therapy with intracerebrally administered genetically modified neural progenitor cells led to increased enzyme activity in oligodendrocytes, correction of astrocytic gliosis, and remyelination (280). As inflammatory mechanisms are involved in KD, anti-inflammatory treatment strategies are being investigated in GLD mice, in combination with HSCT (94,460). Universal newborn screening for KD in New York State and the screening in Illinois as of 2010, dictate the knowing outcome of available treatments. Expert consensus states that presymptomatic children with early infantile KD who are transplanted in the first 3 weeks of life survive longer than those without intervention. The vast majority eventually develop progressive neurologic/somatic growth impairment (461).

**104.11.7.1 Hematopoietic Stem Cell Transplantation.** The only available treatment for infants with early infantile KD is hematopoietic cell transplantation (HCT), typically using umbilical cord blood. HSCT in the Twitcher mouse and other animal models for KD significantly extends life span, normalizes psychosine levels, and improves central and peripheral neuropathological findings and motor ability. That being said, all transplanted animals have ultimately died of KD. In infants diagnosed with KD, HSCT significantly increases life span and ameliorates neurological outcome when performed before disease onset (282). In most cases, there is only a mitigation of disease severity. Despite improvement in white matter myelination after HSCT, children with KD still develop motor difficulty due to peripheral nerve involvement, as well as persistent cognitive deficits. Eighty percent do not walk independently at the age of 2 years (462). When the patient is already symptomatic, HSCT does not significantly modify the course of the disease (282,463). The efficacy of transplantation in later onset GLD remains less well delineated. Patients with later onset disease are likely to benefit from transplantation if undertaken early in the course of their disease, although no long-term data are available (464). HSCT leads to improvement in peripheral nerve conduction abnormalities in patients, suggesting remyelination of nerves occurs, particularly if performed early in the course (465). Allogenic HSCT has been beneficial; however, no transplanted patient achieved complete normalization of peripheral nerve

function, despite well-documented remyelination of the CNS and PNS (466). HSCT should be viewed as a treatment that attenuates the clinical course and improves survival, but is not curative. The majority of presymptomatic children transplanted for KD have developed motor and language deterioration, the cause and extent of which is unknown (461). Animal studies in Twitcher mouse suggest a possible role for IL-6 in the pathogenesis of GVHD in transplanted patients with GLD (467). The exposure of neonatal brain to irradiation performed prior to BMT, can lead to long-lasting alterations of postnatal neurogenesis and myelination, which might contribute to the progression of disease in myelin mutants and reduction in the success of BMT (468). In addition, inflammation, neurotoxic effects of preparative drugs for transplantation, and other factors may contribute to neurological deterioration. HSC-based gene therapy is being explored for GLD. Forced GALC expression is toxic to HSCs and early progenitors, highlighting the need for improved regulation of vector expression. By incorporating microRNA target sequences into a GALC-expressing vector, GALC expression can be suppressed while maintaining robust expression in mature hematopoietic cells. This approach protects HSCs from GALC toxicity and allows successful treatment of the mouse GLD model (469).

**104.11.7.2 Enzyme Replacement Therapy.** Intravenous administration of the deficient enzyme results in increased brain enzyme activity in the Twitcher mouse and prolonged survival times, weight gain, and improved gait (470). Enzyme replacement via direct injection into the brain parenchyma, the ventricles, or the lumbar subarachnoid space has been attempted (463). Peripheral injection of recombinant GALC, administered every other day, results in substantial improvement in early clinical phenotype of the Twitcher mouse. Following ICV administration of GALC, a 16.5% reduction in psychosine is noted. Recombinant GALC reached periventricular regions and sites distant to injection in the cerebral cortex and cerebellum. Animals receiving a single ICV dose at postnatal day 20 survived up to 51 days, compared to control Twitcher mice, which normally live to postnatal day 40–42. So, a single ICV administration of recombinant enzyme can have a significant clinical impact and suggests that lysosomal storage disorders with CNS involvement may similarly benefit from single-dose ICV administration of GALC, improving survival (471).

**104.11.7.3 Gene Therapy.** There is a growing literature on gene therapy in the brain of small and larger animal models with lysosomal storage diseases, although getting the viral vector into the brain remains problematic. The recombinant vector is injected directly into the nervous system. This approach has been successful in models of KD using AAV. A spontaneously transformed progenitor cell line was isolated from an astrocyte-enriched fraction of normal mice, partially characterized and transduced

with a retrovirus-containing mouse GALC cDNA to produce increased GALC activity (20- to 30-fold above baseline). These cells were injected into brains of newborn Twitcher mice. While there was only a modest increase in life span and body weight, there was clear evidence for the correction of astrocytic gliosis, normal-appearing oligodendrocytes, and evidence for remyelination. This treatment resulted in a 5-day delay in the onset of tremors, but only a modest increase in life spans and body weight. This treatment did result in the betterment of brain pathology. This includes an improvement in the appearance of oligodendrocytes with donor cells expressing GALC activity, and a reduction in staining for GFAP, indicating much less astrocytic gliosis (472). In vivo brain viral gene transfer of GALC has only shown modest impact on disease development in Twitcher mice, in spite of GALC LV vectors transduced neurons, oligodendrocytes, and astrocytes with efficiencies above 75% conferring high levels of enzyme activity. GALC accumulated in lysosomes of transduced cells and was also secreted to the extracellular medium. Conditioned GALC medium was able to correct the enzyme deficiency when added to nontransduced Twitcher glial cultures. Mice that received intraventricular injections of GALC vector showed accumulation of GALC in ependymal cells, but no diffusion of the enzyme from the ependymal ventricular tree into the cerebral parenchyma. Significant expression of GALC was detected in neuroglioblasts when GALC LV vectors were injected in the subventricular zone of Twitcher mice. Life span and motor conduction, however, were not significantly ameliorated (473).

**104.11.7.4 Combination Therapies.** Combined therapies will be needed to completely treat GLD. One treatment may help prevent early pathological events such as inflammation and apoptosis, while another may provide long-term supply of GALC activity to oligodendrocytes or replace dead/dying oligodendrocytes. Treatment of the PNS may require an entirely different approach. The combination of BMT and CNS-directed gene therapy may have a synergistic effect in ameliorating certain aspects of GLD. A combination of BMT and AAV2/5 results in improved brain pathology, mean life span, and behavior in mice (474). In the Twitcher mouse, combining L-cycloserine, an inhibitor of 3-ketodihydrosphingosine synthase, the synthetic enzyme of the toxic substance psychosine, and HSCT enhanced life span synergistically (461).

**104.11.7.5 Anti-inflammatory modalities.** Psychosine mediates inactivation of AMP-activated protein kinase (AMPK), which causes lipid alteration in astrocytes and oligodendrocytes. AMPK activator does not rescue oligodendrocytes from psychosine-mediated cell death, but downregulates psychosine-mediated production of NO and the expression of inflammatory cytokines/mediators (iNOS and Cox-2) in primary astrocytes. Loss of oligodendrocytes and the induction of inflammatory disease in KD/Twitcher brain suggest

that the inhibitors of sPLA2 and the inhibitors of inflammatory responses may be potentially therapeutic for KD (475). Mutations in *GALC* can cause GLD by impairing protein processing and/or folding. Pharmacological chaperones, therefore, may be potential therapeutic agents for patients carrying certain mutations (476). There is poor correlation between neuroimaging, neurophysiologic studies, and clinical course. Improvements identified in the white matter on MRI/DTI post-transplant are reported, despite evidence of continued neurologic dysfunction. Similarly, nerve conduction studies improve posttransplant, but clinical deterioration occurs. More sensitive techniques are, therefore, needed to monitor response (461). KD patients who underwent stem cell transplantation within the first month of life showed substantially smaller decreases in anisotropy ratios in four white matter regions than those treated later in the first year of life. These findings correlate well with global assessments of disease progression by neurodevelopmental evaluations and conventional MR imaging. Diffusion-tensor MR imaging offers a quantitative, reproducible method for evaluating white matter abnormalities (458).

## 104.12 METACHROMATIC LEUKODYSTROPHY

### 104.12.1 Introduction and History

MLD arises because of the failure of breakdown of sulfatide and other sulfated lipids primarily in the white matter of the peripheral and central nervous systems. This autosomally inherited illness occurs because of a deficiency in the arylsulfatase A (ASA) enzyme that normally desulfates 3-O-sulfogalactosyl-containing lipids. The accumulated sulfated glycolipids appear brown in tissue sections stained with cresyl violet, hence the name. The pathologic hallmark in humans is extensive demyelination in both the CNS and the PNS. Apparently, the first case of MLD described was by Alzheimer in 1906, followed by other reports from Witte, Scholz, and others (105). Jatzkewitz and Austin described excess sulfatides in tissues from patients. The ASA enzyme deficiency was discovered in 1965. Mehl and Jatzkewitz also confirmed this finding and later also discovered a heat-stable factor that increases enzyme activity several-fold, which we now know is the activator saposin B (385,477,478). Defects in saposin B account for a rare form of MLD with normal ASA activity (479). In 1965, yet another form of ASA deficiency with features of a leukodystrophy, ichthyosis, and a MPS was described, also known as multiple sulfatase deficiency, as seven different sulfatases are deficient (480,481). There are also numerous references to normal individuals with absent or very low ASA levels reported from MLD families. These individuals possess the “pseudo-deficiency” allele (384,482).

### 104.12.2 Clinical Presentation

**104.12.2.1 Late Infantile Variant.** The most well-known type of MLD is the late infantile variant. Additionally, there are juvenile- and adult-onset variants. The late infantile variant presents between 18 and 24 months. Children begin walking, but never outgrow their waddling gait stage. Typically, they have absent ankle jerks due to a peripheral neuropathy, Babinski signs, and the evidence of demyelination on neuroimaging and a peripheral neuropathy. They have optic atrophy, develop cognitive decline, and speech disturbances, only to become quadriparetic and generally do not survive the first decade. Mean age at death is 4.2 years and 5-year survival from onset of symptoms is 52% (483). Many develop seizures late in the course of the illness. They have elevated CSF protein, which is not uncommon in white matter diseases. An unusual occurrence in MLD may be papillomatosis of the gall bladder, which can present as acute cholecystitis or an abdominal mass due to the deposition of sulfatide in the gall bladder (22,484). Very rarely, hemobilia with massive intestinal bleeding occurs, necessitating cholecystectomy (485).

**104.12.2.2 Juvenile Variant.** This type can be early with presentation before 4–6 years, or late juvenile with age of onset between the ages of 6 and 16 years. Symptoms include difficulties with walking, ataxia, progressive spasticity, a peripheral neuropathy more prominent with earlier onset cases, and slow cognitive decline. Spinal fluid protein is also elevated, and optic atrophy may or may not be present. The older onset cases also may have psychiatric issues. Multiple polypoid masses in the stomach and duodenum can result in vomiting, gastrointestinal bleeding, and intussusception, as described in a 5-and-a-half-year-old girl with juvenile MLD (486).

**104.12.2.3 Adult Variant.** Quite frequently, the presenting symptoms may be psychiatric with slow, barely perceptible mental decline. Overt psychiatric illness is rare, but has been reported in two patients presenting with disorganized schizophrenia-like symptoms, and one patient presenting with postpartum depression (487). Peripheral neuropathy may or may not be present. CSF protein can be normal or mildly elevated. A myelopathy with spasticity is also observed in rare cases. Occasionally, ataxia, dystonia, bulbar signs, and tremor can be present, as well as optic atrophy. The course can be as short as a few years and may last for a number of decades. Terminally, patients are quadriparetic and spastic with increased deep tendon reflexes and some do develop seizures (46,250,488,489).

**104.12.2.4 Saposin B Deficiency.** Very few cases have been described. The clinical picture resembles that of ASA deficiency, but enzyme activity levels are normal. The age of onset is quite variable. Sphingolipid activator protein B deficiency is more common than ASA-deficient MLD in Arabs, a notion that has potential diagnostic and preventive implications (490). A high index of suspicion in

the setting of a degenerative demyelinating process and normal ASA enzyme levels leads to diagnosis, which can then be confirmed by the measurement of urine sulfatides, the assessment of sulfatide metabolism in cultured fibroblasts, or by direct sequencing of the gene (491).

**104.12.2.5 Multiple Sulfatase Deficiency.** A clinical picture similar to late infantile MLD with white matter changes on neuroimaging, and a Hurler-like MPS appearance with coarse facial features, deafness, dysostosis multiplex, and organomegaly, are consistent with the diagnosis of multiple sulfatase deficiency (MSD). The most common form is an infantile variant with mild MPS features, clear corneas, ichthyosis, optic atrophy, and retinal degeneration with rare cherry-red maculae. There is a neonatal severe form with prominent MPS features, an early infantile variant described in children from Saudi Arabia less than 1 year of age with dwarfism, severe MPS changes of dysostosis, craniosynostosis, hydrocephalus, and cervical cord strangulation, but the absence of ichthyosis or retinitis. MSD is due to the deficiency of seven different sulfatases, ASA being one of them. The defects arise because of a change in posttranslational modification affecting all sulfatases (see “Genetics” and “Biochemistry” sections later in this chapter) (480,481).

**104.12.2.6 Laboratory Tests.** *Routine Tests:* These are normal with the exception of CSF protein, which is elevated in the late infantile and early juvenile forms. The diagnosis is usually made based on ASA enzyme activity, urine sulfatide measurement, sulfatide turnover in cultured fibroblasts, and in some instances molecular DNA analysis.

*Neuroimaging:* Progressive loss of myelin in MLD has characteristic appearances by CT and MRI. The centrum semiovale is almost always involved with low signal on T1-weighted images and bright signal on T2-weighted sections. Arcuate fibers are almost always spared. There is prominent involvement of both frontal and parieto-occipital white matter with occipital regions being severely involved. The cerebellum is involved only in advanced stages of disease (492). A tigroid striped quality to the white matter is also sometimes seen. Proton MRS is abnormal with elevated myo-inositol values and

marked reduction in the *N*-acetyl aspartate peak, which suggests neuronal loss. There is elevation of the lactate peak in the white matter. MRS may provide a valuable tool for measuring the effects of treatment interventions. PET scans have demonstrated low metabolic rates in the thalami (46,489). MLD should be in the differential diagnosis of acute/subacute demyelinating polyneuropathy in children younger than 2 years, even with normal initial brain MRI scans (493). Late infantile MLD can present with marked contrast enhancement of nerve roots at the level of the cauda equina or isolated cranial nerve enhancement without brain white matter involvement at the time of diagnosis, in spite of the presence of clinical signs (494,495).

*Neurophysiology:* The EEG, although normal initially, becomes slow and abnormal. Some patients have epileptiform activity and many patients develop seizures late in the course of the illness (258). Nerve conduction velocities are slowed, particularly in the late infantile and early juvenile types, but can be involved in late juvenile and adult variants. Abnormalities in visual-, brainstem-, and somatosensory-evoked responses have been reported for all types, but are more common in the severe early-onset types. There can be prolongation of interpeak latencies loss of wave components (496).

**104.12.2.7 Pathology.** The pathologic hallmarks of MLD in the CNS are massive demyelination with sparing of U fibers within deep gray structures and metachromatic granules that stain brown with acidified cresyl violet (Figure 104-10). These granules are also observed in peripheral nerves and visceral organs. They appear as spherical structures with a diameter of 15  $\mu$ m. The ultrastructure is quite characteristic and appears as prismatic inclusions that have a herring-bone lattice, which appears cross-sectionally to have a honeycomb pattern. Another type of inclusion body described as Tuffstone-like may also be seen and has been reported in the thalami of adult MLD cases. In the late infantile variant, demyelination of the brainstem and spinal cord are prominent. There is a reduction in the number of oligodendrocytes and a reactive gliosis. The cerebellum is shrunken with the loss of both Purkinje and granule cells. Remaining Purkinje cells have torpedo-like swellings. The peripheral nerves,

**FIGURE 104-10** Metachromatic leukodystrophy: CNS demyelination with sparing of U fibers and metachromatic granules (arrows).

**FIGURE 104-11** Metachromatic leukodystrophy: peripheral nerve with segmental demyelination and metachromatic granules in macrophages and Schwann cells.

particularly in the early-onset severe forms of MLD, show segmental demyelination and metachromatic granules in macrophages and Schwann cells (Figure 104-11). Muscle histology may be distinctive for fiber-type disproportion with the atrophy of type I fibers. There is marked reduction in the thickness of myelin sheaths. Visceral organs, especially those with an excretory function such as the kidneys, the gall bladder, and the testis, accumulate sulfated lipids in adult MLD cases. Liver intrahepatic bile duct cells also contain metachromatic granules.

**104.12.2.8 Biochemistry.** Sulfatide and deacylated sulfatide of white matter are increased in late infantile MLD. It was also increased in cerebellum, brainstem, and spinal cord of a 24-week fetus. In adult MLD, white matter sulfatide is not as high, but gray matter sulfatide is more elevated than it is in late infantile MLD. They are also increased in gall bladder, liver, and kidney. Other sulfated glycolipids such as lactosylceramide 3-sulfate and seminolipid also accumulate, the latter only in testis. Sulfatide is a sulfated ester of galactosylcerebroside with the sulfate joined by an ester linkage to the C-3 hydroxyl of galactose. Formation of sulfatide is maximal during periods of myelination. Galactosylceramide, from which sulfatide is derived, and sulfatide maintain insulator function, are able to undergo hydrophilic and hydrophobic reactions, are active in Na transport, and are involved in binding of GABA, opiates, gp120 of HIV, prionic protein, and  $\beta$ -amyloid to the cell surface. The primary enzyme defect in all forms is in ASA, which is deficient in all tissues and cells from these patients. It is thought that excess sulfatide leads to myelin breakdown because it lowers the critical temperature for myelin. Late-onset forms of MLD presumably have residual enzyme activity such that sulfatide accumulates at a lower rate than early forms of MLD (260,497). Lysosulfatide is a cytotoxic compound in cell culture and may be involved in the pathology of MLD. ASA-null mutant mice show increased brain lysosphingolipid. Furthermore, a developmental increase of lysosulfatide is observed. Lysosulfatide is considered to be a possible pathogenic agent

in MLD contributing to severe demyelination occurring in patients. The mechanism of involvement is not known (498).

Transgenic ASA-deficient [ASA(-/-)] mice overexpressing the sulfatide synthesizing enzymes UDP-galactose:ceramide galactosyltransferase (CGT) and cerebroside sulfotransferase (CST) in neurons have been generated to provoke neuronal lipid storage. CGT-transgenic ASA(-/-) [CGT/ASA(-/-)] mice accumulate C18:0 fatty acid-containing sulfated GalCer in the brain. Histochemically, an increase in sulfolipid storage could be detected in central and peripheral neurons of both CGT/ASA(-/-) and CST/ASA(-/-) mice compared with ASA(-/-) mice. CGT/ASA(-/-) mice developed severe neuromotor coordination deficits and weakness of hindlimbs and forelimbs. Light and electron microscopic analyses demonstrated nerve fiber degeneration in the spinal cord of CGT/ASA(-/-) mice. CGT/ASA(-/-) and, to a lesser extent, young ASA(-/-) mice exhibited cortical hyperexcitability, with recurrent spontaneous cortical EEG discharges lasting 5–15s. These observations suggest that sulfatide accumulation in neurons contributes to disease phenotype (499).

Concentrations of cholesterol and its metabolites were determined in ASA-deficient [ASA(-/-)] mice, an animal model of MLD. A significant reduction in cholesterol content in the brain of adult ASA(-/-) mice compared to wild-type controls was observed. This was not due to the loss of myelin because ASA(-/-) mice do not demyelinate. Other cholesterol metabolites were not changed significantly in ASA(-/-) mice, except for an increase in lathosterol. Moreover, reduced cholesterol levels were found in tissue samples from two juvenile MLD cases. Since high cholesterol levels are important for myelination and various cellular processes, such as vesicular trafficking and signal transduction, reduced cholesterol might be an important factor in the molecular pathology of MLD. Arylsulfatase A and B proteins exist on the cell surface in mammalian tissues, including sinusoidal endothelial cells, hepatocytes, and sinusoidal macrophages (Kupffer cells), as well as the lysosome. They also colocalize with heparan sulfate proteoglycan. The extracellular localization of ASA may provide new insights for MLD (500).

### 104.12.3 Genetics

All MLD variants, with the exception of cases due to saposin B defects and cases with MSD, are inherited as autosomal recessive traits, and are due to allelic mutations affecting ASA. The actual defect in MSD remains unknown but affects the serine at position 69 in ASA, which should become formylglycine that is necessary for catalytic function of all sulfatases. In Sweden, the incidence of the disease is 1 per 40,000. It is lower than that in other European countries. Habbani Jews originating from Yemen have an incidence of 1 in 75 cases due to a high carrier rate and common consanguinity (501).

Arabs from an area north of Nazareth have an incidence of 1 in 8000. Two groups with high incidence are Eskimos (1/2500) and Navajo Indians (1/6400). The latter two groups carry the same genetic defect (502).

It is important to understand the genetics of ASA pseudodeficiency since the correct interpretation of ASA activity test results is crucial to correct diagnosis. This is a misnomer as the pseudo allele codes for a low-enzyme activity variant (5–10% of normal) without clinical consequences. This pseudo allele often is present in families that also carry a true MLD allele. The frequency of the pseudo allele in Europe can be as high as 10–20%. The incidence for heterozygotes carrying one pseudo and one ASA allele is 1 per 1500 individuals. A small proportion of these have neurological complaints are not related to MLD. The pseudo allele has two polymorphisms: (1) the first causes loss of one of three glycosylation signals resulting in a slightly shorter protein (N350S), and (2) the second polymorphism affects the polyadenylation signal, which precludes generation of the long ASA transcript. The N-glycosylation defect results in loss of 50% of ASA activity. Presence of the second polymorphism causing loss of the polyadenylation signal results in ASA activity that is 10% of normal. More than 68 mutations have been described in MLD. Three alleles account for most European cases. One of these alleles, c.459+1A→G, which results in loss of a splice-acceptor site, is found among Arabs. Seven of the MLD-causing mutations occur in the background of a pseudo allele. It is really the amount of residual activity determined with a sulfatide loading test that correlates best with disease severity. Patients with one pseudo and one MLD allele have 5–10% enzyme activity and are normal. Adult MLD patients have 2–5% enzyme activity, and patients with late infantile MLD have even lower activity from 0 to 2% determined in this manner.

In a multicenter European study with different forms of the disease, c.459+1G→A was found in 25%, whereas p.P426L was identified in 18.6%. Mutation c.459+1G→A was most frequent in late infantile MLD patients (40%), while p.P426L was most frequent in adults (42.5%). The mutation p.P426L was also found in a few late infantile patients (0.9%), and c.459+1G→A was present in some adults (9%). Mutation c.459+1G→A is more frequent in countries situated at the western edges of Europe. Mutation p.P426L is most prevalent in The Netherlands, Germany, and Austria. In other Central European countries, the frequency of both c.459+1G→A and p.P426L is 8–37.5% (503). P426L homozygotes present with progressive gait disturbance caused by spastic paraparesis or cerebellar ataxia. Mental disturbance was insignificant at the onset but became more apparent as the disease evolved. Reduced peripheral nerve conduction velocities and higher residual ASA activity are common (504). The I179S allele predisposes to psychiatric symptoms. A novel mutation, T279I, correlates with schizophrenia-like symptoms, neurological signs, and cognitive impairment

early in the course and fast progression toward dementia (505). Similarly, compound heterozygous missense mutations (p.G99D/p.T409I) may correlate with frontal lobe dysfunction manifesting as disinhibition and impaired executive function (506).

Two sisters with adult-type MLD developed psychiatric symptomatology, but differed in the expression of psychotic and depressive symptoms. Association studies had indicated that polymorphisms in genes encoding serotonin/dopamine transporters and receptors are related to symptoms of schizophrenia/depression, hence both sisters were genotyped for these candidate genes. The sisters shared dopamine receptor D2 (DRD2) c.1047GG (p.311Ser/Ser) and c.-141Cins/ins polymorphisms, which are also associated with schizophrenia, but differed in the serotonin transporter gene-linked polymorphic region and serotonin. A large sample is needed to have sufficient statistical power to develop a meaningful hypothesis. This is the first report genotyping candidate genes in MLD patients for psychiatric disorders, although MLD had been proposed as a model for schizophrenia (507). The sulfatide loading test also helps in identification of saposin B-deficient patients. Urine sulfatide excretion can also be used to differentiate these forms from each other. In determining carrier status, it is always best to be aware of the mutations carried by obligate carriers in that family. In prenatal diagnosis also, it is important to determine if the parents carry a pseudo allele as well. Sulfatide loading tests in this instance are extremely helpful (482). The ability to use dried blood spots to measure ASA protein and activity will simplify procedures for collection, handling, and storage of patient samples. The ease of transporting dried blood spots, combined with the diagnostic sensitivity and specificity of these assays, provide a powerful approach to the diagnosis of MLD. After further investigation and validation, these assays may be used for newborn screening for MLD and other lysosomal storage disorders (55,508). Presymptomatic detection of affected individuals may be possible with the introduction of newborn screening programs. The ability to accurately predict clinical phenotype and the rate of disease progression in asymptomatic individuals is essential to assist the selection of appropriate treatment strategies. Incorporating the determination of residual enzyme protein/activity using immune-based assays and metabolite profiling using electrospray ionization-tandem mass spectrometry were performed on urine and cultured skin fibroblasts from patients representing the clinical spectrum of MLD and unaffected controls. Residual enzyme activity in fibroblasts differentiated unaffected controls, ASA pseudo-deficient individuals, pseudo-deficient compound heterozygotes, and affected patients. MLD phenotypes were distinguished by quantification of sulfatide and other altered lipids in urine and skin fibroblasts. This enabled differentiation of the late infantile form of the disorder from the juvenile/adult forms. Prediction of the rate of disease progression for MLD requires a

combination of information on genotype, residual ASA protein/activity, and the measurement of sulfatide and other lipids in urine and cultured skin fibroblasts. A combined approach using genotype determination, where appropriate, followed by urine analysis combined with ASA and lipid measurements in cultured skin fibroblasts will provide good prediction of the age of onset and the rate of progression (509). Patients homozygous for the null allele suffer from the late infantile form. Heterozygosity for a null allele and a non-null allele are associated with the juvenile form, and homozygosity for non-null alleles is more frequent in attenuated adult-onset form. Genotype and mutation studies are valuable tools for accurate selection of patients for new therapies as well as for precise prognostication in presymptomatic cases (510).

A patient with adult-onset MLD, heterozygous for a novel nonsense mutation (C38X) (TGC/TGA) and a known missense mutation (T409I) (ACT/ATT), showed severely decreased nerve conduction velocities without obvious external clinical signs of neuropathy (511). On the other hand, a novel mutation (F219V) associated with an adult-onset case of MLD presented with progressive psychocognitive impairment without clinical or electrophysiologic signs and only minor morphologic signs of peripheral nerve involvement (512). A recent report described a Korean male with a novel heterozygous splicing mutation (c.1101+1G>T) in intron 6 and a heterozygous missense mutation in exon 2 (c.296G→A; Gly99Asp). The patient's elder brother who died of MLD is believed to have had the same mutation, which may be correlated with a rapidly deteriorating and lethal clinical course (513). Recently reported novel mutations in the Indian population include c.752\_753insT (p.Leu251fs) and c.98ANC (p.Tyr33Ser) that cause a late infantile form; c.508GNA (p.Gly170Ser) and c.1288GNT (p. Asp430Tyr) that result in an early-juvenile form; and c.1300GNA (p.Asp434Asn) causing a late-juvenile form (317). A first mutation of the ASA gene has been recently described in the Tunisian population. This was a novel missense mutation resulting in the substitution of Trp with Gly p.W124G and causing a late infantile form of MLD (514). In a study involving unrelated Italian patients, 11 new ASA alleles (c.53C>A; c.88G>C; c.372G>A; c.409\_411delCCC; c.634G>C; [c.650G>A; c.1108C>T]; c.845A>G; c.906G>C; c.919G>T; c.1102-3C>G; and c.1126T>A) were discovered (515). Other reports from Italy identified three novel mutations: Ser406Gly, Glu329Tr associated with late infantile MLD, and Leu52Pro with juvenile MLD (516). In addition, eight newly identified ASA mutations in the same population were identified and characterized through LV vector-based expression studies in cell lines and ASA-defective murine fibroblasts. The novel mutations c.155T>C, c.504C>A, c.634C>G, c.911C>T, c.919G>A, 1216A>G, c.1222\_1223delAC, and c.412C>G have resulted in null or very low residual

activities, whereas c.412C>G showed residual activity (517). In a study of Polish patients with different types of MLD, six novel mutations were identified: one nonsense (p.R114X), three missense (p.G122C, p.G293C, p.C493F), and two frameshift mutations (g.445\_446dupG and g.2590\_2591dupC). Substitutions p.G293C and p.C493F and duplication g.445\_446dupG caused a severe reduction of enzyme activity in transient transfection experiments in mammalian cells (less than 1% of wild-type (WT) ASA activity). Duplication 2590\_2591dupC preserved low-residual ASA activity (10% of WT ASA) (518). Molecular characterization of a cohort of 26 MLD patients allowed the identification of 18 mutations, 10 of which are rare and 8 novel: 1222–23delAC Asp407fs, 155T.C Leu52Pro, 504C.A Cys168STOP, 634G.C Ala212Pro, 911C.T Thr304Met, 1216A.G Ser406Gly, 412C.G His138Asp, 919G.A Glu307Lys (519). Two novel frameshift mutations (c.179\_180dupCA and c.1338dupC) were recently described in Chinese patients (520).

Juvenile MLD may rarely present with atypical, sometimes episodic, symptoms and findings. One patient demonstrated acute intermittent encephalopathic episodes for 1 year after having received the diagnosis of MLD at the age of 6 years. He was a compound heterozygote for the c.1277C>T (p.Pro426Leu) MLD mutation, and had a novel complex deletion/insertion mutation (c.1268\_1278delATGAGCCCC CGinsCCCCCCCC). Another patient homozygous for the mutation (c.1071A>G) presented at the age of 5 years with acute hemiparesis, which resolved in 3 weeks and developed progressive neurological deterioration after 2 years of remission. The episodic manifestations in both patients were associated with acute, resolving cerebral lesions on MRI accompanying or preceding the classical demyelinating lesions of MLD (521). A novel mutation at codon 1204 consisting of one base insertion or c. 1204+1G > results in a complete loss of enzymatic activity of ASA and subsequently a late infantile type MLD patient. MRI of the affected patient demonstrated the “tigroid” or “leopard-skin” demyelination pattern (522).

A patient with prosaposin precursor gene defects with saposin B deficiency presented with a MLD-like disorder, but had normal arylsulfatase activity. The SapB-deficient patient was a compound heterozygote. A 2-bp deletion (c.828–829delGA) in exon 8 on one allele resulted in the complete absence of the transcript, most likely due to nonsense-mediated decay, so no prosaposins or saposins could be generated from this allele. On the other allele, the c.577-2A>G splicing mutation led to the formation of two alternative transcripts, both of which carry an in-frame deletion of a portion of the SapB domain. This mutation exclusively affects the SapB domain and did not result in the deficiency of other saposins. In keeping with this finding, the biochemical and clinical phenotype in this patient was consistent with an isolated absence of SapB (321). Prosaposin activator gene analysis in

four unrelated Saudi families uncovered a homozygous mutation, a 722G>C transversion resulting in C241S change. This suggests that sphingolipid activator protein B deficiency is likely to be a common cause of MLD in this population. C241S is a prevalent mutation in Arab patients with MLD, and can be used for rapid diagnosis and preventive interventions (490).

A deletion on one chromosome and on a mutant allele on the other may cause an autosomal recessive disease. Patients with mental retardation, dysmorphic features, and low catalytic activity of ASA are described. One patient had a pathogenic mutation in ASA and succumbed to MLD. The other patient had a pseudo allele, which does not lead to MLD. The presenting clinical features and low ASA activity were explained in each patient, by a deletion of 22q13 and, thereby, of one allele of ASA (523). More than 100 cases of the 22q13 deletion syndrome (21,176,301) and ~90 cases of ring chromosome 22 [r(22)] have been reported (272,376). The ring formation of chromosome 22 is assumed to be associated with concomitant loss of telomeric material. Gene dosage studies have shown partial deficiency of ASA in patients with deletion of 22q13 (209). The patient reported (377) had a leukocyte activity of ASA at 47% of the normal. Whether the progressive peripheral neuropathy in their patient was related to this low ASA activity and MLD remained unanswered. Mental and physical regression in two of five patients with r(22) is described (272). One of the patients also had a diagnosis of bipolar affective disorder at the age of 12. The activity of ASA was not measured. The other patient had low ASA level, but molecular investigation for MLD was not performed. In 1995, a patient was reported with MLD and a r(22) deleted for ASA (524). ASA on the other allele carried a pathogenic mutation. The concurrence of MLD and the deletion of 22q13 may not be rare. It is suggested that ASA be measured in patients with 22q13 deletion syndrome for proper counseling, prognosis, and treatment (523).

#### 104.12.4 Animal Models

No naturally occurring animal models exist, but a transgenic mouse has been created that demonstrates sulfatide storage in the brain, kidney, and other organs. The neuropathologic lesion is similar to that in humans with more sulfatide deposited in the white matter than in the gray, loss of Purkinje cells, and a peripheral neuropathy. There is astrogliosis in the white matter but normal glia in mice of 1 year of age. By the age of 2, they demonstrate glial activation. There is a marked difference from human disease, however, in that the mice do not show CNS demyelination. They have a milder phenotype than one expects. Gene therapy experiments have shown variable positive results with decreased storage and mild clinical improvement (386). A second mouse model of MLD was optimized by transgenic expression of an inactive hASA mutant on the ASA-/- background.

Transgene expression does not alter the MLD-like phenotype, but confers absolute immune tolerance to wild-type hASA. The novel mouse strain represents an MLD variant with residual enzyme levels, which account for the vast majority of MLD cases. In contrast to conventional ASA-/- mice, the new strain allows for long-term ERT in the absence of immunological side effects (525).

#### 104.12.5 Treatment

Currently, no available treatment can reverse the fatal outcome of this devastating disease, and therapy is only supportive. Physical therapy, muscle relaxants such as vigabatrin and baclofen reduce spasticity. The former drug and other antiepileptics reduce seizures when present. BMT may have beneficial effects in the later onset forms of the disease but has shown no benefit for early-onset, late infantile MLD (256). Only a minority of transplanted MLD cases have been repeatedly reported in small series or as single-case reports. The posttransplant follow-up is short and does not allow proper interpretation of the clinical outcome. HSCT proved ineffective in patients with overt neuropsychological and/or neurological signs or in those with early-onset/aggressive infantile forms. Late infantile MLD cannot be effectively treated by HSCT of any type, cord blood or BM (20,56,141). The claim that late infantile MLD patients transplanted when asymptomatic or at least 1 year before the age of onset, will remain asymptomatic, has never been proven. Some case reports have suggested that BMT can stop the progress of juvenile MLD and may be indicated early in the disease as shown by the improvement in clinical, electrophysiological, and neuroradiological data obtained over long-term periods (526). Despite full engraftment and normalcy of enzymatic activity in juvenile/adult forms, the only benefit might be prolonged survival in selected cases, but without improved or stabilized quality of life (262,263,527,528).

In few patients, UCBT has been beneficial in stopping the progression of the disease clinically, neurophysiologically, and pathologically. Whether these are temporary or permanent effects will require long-term monitoring (529). The response to unrelated UCBT appears to depend on the stage of disease in each child at the time of transplant. A relationship between an individual's genetic makeup and his/her response to UCBT cannot be ruled out, so caution is advocated when recommending this modality to other families with MLD (530). Surprisingly, intravenous ASA enzyme replacement trials in the transgenic mouse model, given once a week for 4 weeks, result in reduced sulfatide storage in viscera, spinal cord, and brain. Efficacy in humans has not yet been tested, although this approach seems quite promising (531). Currently, a phase I/II trial is ongoing to evaluate the safety, efficacy, and pharmacokinetics of rhASA administration in patients with late infantile MLD. Efficacy data are still unavailable. There

are significant limitations such as the BBB, which limits access of the recombinant product to the nervous tissues. Furthermore, recurring intraparenteral administration of an exogenous protein carries the risk of inducing an immune response against the enzyme, thus reducing the therapeutic impact of the treatment (528). Therapeutic trials in knockout mice showed that ERT was tolerated without side effects and improved disease manifestations in a dose-dependent manner (532).

Injection of recombinant human ASA (hASA) in ASA-deficient mice reduced sulfatide storage in peripheral nerves and was effective in reducing sulfatide storage in the brain and spinal cord of treated mice. PNS symptoms prevail in infantile forms of MLD, and are nearly always present in other forms of MLD. ERT improved neuro-motor coordination capabilities and normalized peripheral compound motor action (531). ERT might have important clinical benefits if given in combination with other therapeutic approaches targeting the brain, but also in patients who have undergone allogeneic HCT. One may anticipate that early ERT treatment might have long-term clinical benefits in MLD patients, particularly if used to treat/prevent the motor disability due to the involvement of the spinal cord and PNS, not amenable to cell or gene therapy (533). ICV ERT at low dose reverses previously intractable ataxic symptoms of MLD mouse models and results in marked histological improvement, without adverse immunological effects, and may be an option for future treatment of MLD (534).

**104.12.5.1 Gene Therapy Strategies.** Intracerebral injection of adenovirus, AAV, and LV vector encoding hASA corrects the biochemical, neuropathological, and behavioral abnormalities in ASA-deficient mice without adverse effects, when AAV-ASA injections were performed at an early stage of the disorder. Injection at a later symptomatic stage prevented sulfatide storage and neuropathological abnormalities; however, neuromotor disability was unchanged (535–538).

**104.12.5.2 Cell-Based Therapy within the Brain.** An alternative approach to gene therapy is the direct engraftment of oligodendroglial progenitors or neuronal progenitors and of ES cells into the CNS of MLD patients, taking advantage of the regenerative capacity and cross-corrective activity of these cells. Mouse oligodendrocyte progenitors can be grafted into neonatal MLD brain, and ~10% of these cells survive in adult-treated mice. Transplanted ASA-deficient mice display reduced sulfatide accumulation in the CNS. This results in the prevention of motor deficits and electrophysiological abnormalities that characterize ASA-deficient mice. Migration and targeting of oligodendroglial progenitors into white matter was significantly greater when these cells were intravenicularly transplanted in neonate MLD mice. Transplanted cells seemed to tolerate the toxic accumulation of sulfatides, although this is minimal at birth in ASA-deficient mice. The distribution of these cells was more restricted when transplantation was performed 2 months

after birth (539). Neural progenitor cells (neurospheres) prepared from the striatum of E14 embryo ASA-deficient transgenic mice were transduced with a LV vector carrying ASA cDNA, and injected into the brain parenchyma of adult ASA-deficient mice (540). Transduced neurospheres retained their potential for differentiating into neurons, astrocytes, and oligodendrocytes in vitro. One month after injection, transduced cells were detectable in the brain, and partial reduction of sulfatide was observed. ASA enzyme was present in both transduced and nontransduced cells, suggesting that genetically engineered neural progenitor cells (neurospheres) could potentially be used for ex vivo therapy in MLD. Transplanting engineered murine ES cells to overexpress the hASA in neonatal ASA-deficient mice resulted in a reduction in sulfatide accumulation up to 175  $\mu$ m from the donor cell, and in vivo differentiation of the grafted cells into astrocytes and oligodendrocytes (541). These experiments demonstrate that ES cells may constitute a potential donor source for cell-mediated ASA delivery. Human MSCs have already been infused into patients following HCT for MLD. MSCs were isolated and expanded from a BM aspirate from the original donor for HCT. Four patients showed significant improvements in nerve conduction velocities after MSC infusion (533).

In vitro treatment with encapsulated cells overexpressing ASA was able to correct ASA deficiency in MLD skin fibroblasts. The implant of microcapsules within the brain could be a potential new therapeutic approach along with ERT. Cell encapsulation would target the CNS whereas ERT would reach the PNS. Continued studies are needed for perfecting timing, routes, and methods of delivery of gene/proteins to their targets in the brain and the PNS. PNS symptoms prevail in infantile forms of MLD, and are nearly always present in other forms of MLD (542).

## 104.13 FABRY DISEASE

### 104.13.1 Introduction

Fabry disease is an X-linked recessive lysosomal storage disease associated with systemic deposition of neutral GSLs, due to defects in the enzyme  $\alpha$ -galactosidase A (543). It was first described by Anderson from England and Fabry from Germany in the 1800s.

### 104.13.2 Clinical Presentation

Clinical onset typically starts during childhood or adolescence, but often is delayed until the third decade. The majority of FD complications are nonspecific and include left ventricular hypertrophy, conduction abnormalities, vascular spasms, proteinuria, and renal insufficiency, which are the reasons behind FD remaining largely underdiagnosed. Female carriers are at risk of developing disease, but this tends to be milder and more slowly

progressive than in males, although some women can display the entire range of clinical manifestations (544). Excruciating pain is the most incapacitating symptom of the disease, and can be episodic or constant. The pain begins in childhood in parallel with disease onset, and is a burning pain starting at the palms and soles of the feet radiating to other parts of the body and is termed acroparesthesias. Fever, exercise, fatigue, and stress trigger painful crises. Patients also suffer from hypohidrosis or anhidrosis and fevers. Another hallmark is the development over time, typically just before or around puberty, of angiokeratomas or angiokeratoma corporis diffusum in a bathing trunk distribution often involving the buttocks and scrotum, and sometimes the hips, thighs, umbilicus, and mucosal surfaces (524). Cardiac involvement is common and affects valves (mitral insufficiency), ventricles (left ventricular enlargement), and the conduction system (376). EKG changes are not due to necrosis, but due to GSL deposition in the myocardium. Patients may present with angina pectoris, dyspnea, palpitations, or syncope. Angina is often reported, but the incidence of epicardial coronary stenosis is not a dominant feature. Small vessel disease can occur. With the progression of the disease, patients die due to heart failure. Some patients manifest the milder “cardiac variant” in which cardiovascular symptoms exist in the absence of acroparesthesias or skin manifestations. This implies that some patients with unexplained myocardial hypertrophy may have undiagnosed FD. Cardiologists should play a key role in suspecting and diagnosing FD. Cerebrovascular disease results from multifocal small vessel involvement, and may end in thrombosis, transient ischemic attacks, basilar artery aneurysm, seizures, aphasia, hemiplegia, and hemianesthesia. MRI and proton MRS are useful in evaluating cerebrovascular disease (216,545,546). Conventional MRI shows micro- and macroangiopathic changes such as severe and progressive white matter lesions at an early age on T2- and FLAIR-weighted images, increased signal intensity in the pulvinar on T1-weighted MRI, as well as tortuosity and dilatation of the larger vessels (dolicho-ectasia). DTI shows brain tissue alterations predominantly in the periventricular white matter. DTI is more sensitive in detecting changes than conventional MRI. DTI measurements could provide appropriate surrogate parameters with which to monitor the natural history of structural brain involvement and potential effects of therapy such as enzyme replacement (547). GSL deposition in the kidney results in proteinuria, with progressive deterioration in renal function and the development of azotemia by middle age. Recently, kidney biopsy data have shown early renal histologic changes in pediatric patients, and kidney dysfunction, primarily proteinuria, is more common in girls. Renal disease with presentation of an ischemic kidney with no albuminuria has been reported (548). Currently, the recommendation is to evaluate systematically all children in registries and to measure albumin excretion

rates regularly and precisely. Renal biopsy could be a method to follow disease progression and responsiveness to treatment. No adequate data on the timing of ERT and the benefits of renal biopsies exists. Currently, it is recommended to perform follow-up noninvasive renal function tests such as three consecutive early morning urine samples for microalbuminuria, a marker of early renal disease (549). Birefringent lipid globules with characteristic “maltese crosses” are observed in the urine in desquamated cells by polarization microscopy. MRI reveals loss of corticomedullary differentiation. Death results from uremia. Gastrointestinal disease due to GSL deposition in intestinal small vessels and in autonomic intestinal ganglia leads to symptoms of diarrhea, abdominal pain, flank pain, nausea, and vomiting. Airflow obstruction, reduced diffusing capacity, and a reduction in the  $V_{\max}$  values may lead to chronic bronchitis, wheezing, and dyspnea. Minor changes are seen on the EEG and EMG. The cornea, lens, conjunctiva, and retina are affected. Spoke-like opacities in the corneas and characteristic lenticular inclusions (290,550) are evident by slit-lamp examination. Conjunctival vessels are tortuous and prominent (Figure 104-7) (551). Retinal infarcts are often present. Decreased erythrocyte survival often leads to anemia. Musculoskeletal involvement is common. There can be damage to the distal interphalangeal joints with limitations of that joint, avascular necrosis of the head of femur or talus, and the involvement of the metacarpal, metatarsal, and temporomandibular joints (48). Osteonecrosis is rarely reported in patients with FD (552). Hearing impairment and tinnitus may be present. Priapism has been reported in ~20 males from the Fabry registry. Derangement in the nitric oxide (NO) pathway may be responsible for this (553). FD is probably underdiagnosed, and the identification of undiagnosed Fabry patients represents a major challenge because heterogeneous phenotypes exist in male and female patients. Females with FD who present with pain are often ignored because the disorder is X-linked. Patients must be identified and treated to improve the quality of life and to protect from organ damage with ERT (554).

### 104.13.3 Pathology

Deposition of crystalline GSLs in endothelial cells of all areas of the body occurs in FD. These lipids show birefringence with characteristic “maltese crosses” under polarization microscopy. Deposition occurs in lysosomes of endothelial, perithelial, and smooth muscle cells of blood vessels, and less so in reticular and histiocytic cells. In the kidneys, GSLs accumulate in the epithelial cells of the glomerulus and of the distal tubules. Lipid-laden tubular epithelial cells desquamate and are detected in the urinary sediment. Renal blood vessels are extensively involved and arterial fibrinoid deposits are very common. GSL deposition occurs in the liver sinus epithelial cells and Kupffer cells, but not in hepatocytes. In the

heart, deposition occurs in myocardial cells and valvular fibrocytes, resulting in cardiac disease (283). Endomyocardial biopsy shows optically empty myocytes on light microscopy and dense osmiophilic bodies constituted of globotriaosylceramide on electron microscopy. Vascular ischemia and lipid deposition in the perineurium of peripheral nerves lead to a painful peripheral neuropathy with documented conduction abnormalities (555). Involvement of sweat glands due to lipid deposition and an inability to sweat raises core temperatures of patients during heat and exercise, exacerbating their painful small myelinated fiber and unmyelinated fiber neuropathy. Immunohistochemical studies using a sensitive anti-globotriaosylceramide monoclonal antibody revealed a selective pattern of neuronal involvement with deposition in the spinal cord and ganglia, brainstem, amygdala, hypothalamus, and entorhinal cortex, with sparing of adjacent areas. Many other organs, including the eyes, adrenals, gastrointestinal tract, prostate, testes, urinary bladder, and thyroid, demonstrate the involvement of blood vessels, smooth muscles, ganglia, and nerves.
